## 2000 Workshop on Boundary Layer Transition and Unsteady Aspects of Turbomachinery Flows

## The NASA STI Program Office . . . in Profile

Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the Lead Center for NASA's scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA's institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA's counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.
- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.
- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.
- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.
- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services that complement the STI Program Office's diverse offerings include creating custom thesauri, building customized data bases, organizing and publishing research results . . . even providing videos.

For more information about the NASA STI Program Office, see the following:

# Minnowbrook III 2000 Workshop on Boundary Layer Transition and Unsteady Aspects of Turbomachinery Flows

John E. LaGraff and David E. Ashpis, editors

Proceedings of a workshop  
held at the Syracuse University Minnowbrook Conference Center  
Blue Mountain Lake, New York  
August 20–23, 2000

National Aeronautics and  
Space Administration

Glenn Research Center

---

April 2002

## Acknowledgments

### Workshop Sponsors

The workshop co-chairs would like to express their appreciation for financial support given to the workshop and to participants by the following groups and individuals:

U.S. Air Force Office of Scientific Research (USAFOSR)  
Thomas Buetner, Grant AFOSR-49620-00-1-0184

NASA Glenn Research Center  
Lou Povinelli and David Ashpis, NASA Grant NAG3-2309

European Office of Aerospace Research and Development (EOARD)  
Charbel Raffoul, USAFOSR, Window-on-Science Program

Asian Office of Aerospace Research and Development (AOARD)  
Koto White, USAFOSR, Window-on-Science Program

Syracuse University  
Ben Ware, Vice President, Research and Computing  
Edward Bogucz, Dean of Engineering and Computer Science

### Local Organizing Support

Special praise is due to Ms. Linda Wakeman who devoted long hours and great care to the processing of the hundreds of details required for a successful workshop. Acknowledgment for help with logistics by students Leonardo Biagioni and Greg Lisnyczyj is also well deserved.

### Proceedings

Special thanks to Lori Feher, Editorial Assistant, Pat Webb, Publishing Coordinator, and Caroline Rist, Desktop Publisher, of LTID Publishing Services at NASA Glenn, for their dedication in producing this volume.

## PREFACE

On August 20–23, 2000, over 40 attendees participated in a workshop entitled “Minnowbrook III—Workshop on Boundary Layer Transition and Unsteady Aspects of Turbomachinery Flows.”

Workshop co-chairs were

John E. LaGraff, Syracuse University, Syracuse, New York, U.S.A.

Terry V. Jones, Oxford University, Oxford, U.K.

J. Paul Gostelow, University of Leicester, Leicester, U.K.

The sessions were held at the Syracuse University Minnowbrook Conference Center in Blue Mountain Lake, New York, and followed the theme, venue, and format of two earlier workshops held in 1993 and 1997. Earlier themes focused on improving the understanding of late-stage (final-breakdown) boundary-layer transition. The specific engineering application of improving design codes for turbomachinery was encouraged by the attendance of representatives from gas turbine manufacturers.

The format of the workshop was intentionally kept informal to encourage presentations that would include a wide range of material spanning a level of formality from previously published work to work-in-progress or even future/proposed work. We did not want to inhibit presentation of relevant material for artificial reasons of normal publication restrictions. Written papers were not requested. Abstracts and copies of figures were the only written records of the workshop aside from a specifically commissioned summation paper prepared after the workshop and transcriptions of the extensive working group reports and discussions that followed on the final morning of the workshop. The format of the workshop was also unusual in that nearly as much time was allowed for discussions as was allowed for the presentations. Groupings of three or four papers were followed by a large block of discussion time.

The workshop proceedings are arranged in the form of a booklet and an accompanying CD-ROM. The booklet includes abstracts and transcripts of the plenary discussion and the summary session. The CD-ROM contains all the viewgraphs presented as well as the materials in the booklet. The materials are organized according to the workshop sessions. The workshop summary and the plenary-discussion transcripts clearly highlight the need for continued vigorous research in the technologically important area of transitional and unsteady flows in turbomachines.

John E. LaGraff, Syracuse University

David E. Ashpis, NASA Glenn Research Center

# TABLE OF CONTENTS

Presenters' names in boldface.

## Keynote Presentation

**Roddam Narasimha**, Jawaharlal Nehru Centre for Advanced Scientific Research

*Subtransitions Revisited* ..... 3

## Session 1—Turbomachinery Disturbance Environment

**H.P. Hodson** and R.J. Howell, Whittle Laboratory, University of Cambridge

*High Lift Low Pressure Turbines* ..... 9

**Greg Heitland**, Honeywell Engines and Systems

*Low Pressure Turbine Reynolds Number Effects: Small Engine Perspective* ..... 10

**J. Hourmouziadis**, Berlin University of Technology

*Free Stream Unsteadiness and Turbulence—What is the Difference?* ..... 11

## Session 2—Natural or Bypass Transition?

**G.J. Walker** and J.D. Hughes, University of Tasmania

*Natural Versus Bypass Transition on Axial Compressor Blades—A Need for Reassessment?* ..... 12

R.J. Howell and **H.P. Hodson**, Whittle Laboratory, University of Cambridge

*Separation Bubble Interactions With Turbulent Spots and Wakes in the Turbomachinery Environment at Reynolds Number of Around 130,000* ..... 13

## Session 3—Spots and Calmed Regions

**T.V. Jones** and R.J. Anthony, University of Oxford; and J.E. LaGraff, Syracuse University

*Visualization of Transitional Heat Flux in the Presence of Freestream Turbulence and Pressure Gradient* ..... 14

**Mark W. Johnson**, University of Liverpool

*The Initiation and Development of Turbulent Spots* ..... 16

**O.N. Ramesh**, Indian Institute of Science; and **H.P. Hodson**, Whittle Laboratory, University of Cambridge

*On the Dynamics of the Calmed Region Behind a Turbulent Spot* ..... 17

C. Kittichaikarn and P.T. Ireland, University of Oxford; S. Zhong, University of Manchester; and

**H.P. Hodson**, Whittle Laboratory, University of Cambridge

*The Visualisation and Measurement of the Onset, Turbulent Spot Production Rate, Intermittency and Heat Transfer During Wake-Induced Transition Using Thermochromic Liquid Crystals* ..... 18

## Session 4—Modelling and Computation

**David E. Ashpis**, NASA Glenn Research Center

*The NASA Low-Pressure Turbine Flow Physics Program—A Review* ..... 19

Y.B. Suzen, G. Xiong, and **P.G. Huang**, University of Kentucky

*Predictions of Transitional Flows in a Low Pressure Turbine Using an Intermittency Transport Equation* ..... 20

**Erik Dick**, Ghent University

## SUBTRANSITIONS REVISITED

Roddam Narasimha

Jawaharlal Nehru Centre for Advanced Scientific Research  
Bangalore, India

There are a number of situations where the intermittency distribution within the transition zone shows evidence of a relatively abrupt departure from the standard 2-D distribution.<sup>1</sup> Two situations in which such changes have been observed and are reasonably well documented are those concerned with the flow past an aligned circular cylinder,<sup>2</sup> and flows with strongly varying pressure gradients.<sup>3</sup> In the former case the mechanism is relatively easy to understand. A spot that forms at any point on the surface of the axisymmetric body will in general wrap around the body after propagation for a certain distance downstream<sup>4</sup>. Downstream of the point where this wrapping occurs there is a turbulent sleeve on the body. The length of this sleeve will increase as it propagates downstream, but its width is limited by the circumference of the body. This leads to a change in the regime of the intermittency distribution, from a 2D like law to a 1D like law.<sup>2</sup>

In the second case rapid changes in the pressure gradient can lead to a situation where spot propagation characteristics can also change correspondingly. It is well known for example that an adverse pressure gradient tends to increase the spot spread rate dramatically;<sup>5</sup> similarly a sufficiently strong favorable pressure gradient or a relatively low Reynolds number can suppress spot growth.<sup>6</sup> It is of course possible that such changes will occur continuously, but an interesting observation is that, at least in certain situations, the changes are relatively rapid, and may be related to a quick shift from subcritical to supercritical states or vice versa in the stability characteristics of the boundary layer.<sup>6</sup>

These different regimes in the transition zone may be said to be separated by *subtransitions*. The evidence for the occurrence of such subtransitions in both flow types mentioned above is reviewed. In flows with pressure gradient, a particularly clear case is presented in Figure 1.

In addition, a detailed analysis of results can be made of the experimental results on a heated axisymmetric body in water reported by Lauchle & Gurney.<sup>7</sup> These measurements provide strong evidence for subtransition: a gradual increase of intermittency in the initial 2D region is followed by a sharp and rapid increase downstream (Figure 2). Taking the possibility of subtransition into account, a model has been formulated<sup>8</sup> for the variation of intermittency with flow Reynolds number at a *fixed* station on the body, as in the experiments. The transition *onset* Reynolds number (corresponding to the location where intermittency begins to depart from zero), inferred from the data on the basis of this model, shows a continuing increase with the temperature overhead, a trend in close agreement with stability theory; but the axisymmetric body geometry results in a very short transition zone, countering in part the benefits of the appreciable transition delay that does occur due to heating. The analysis incidentally reveals that there can be two spot-wrapping scenarios, one involving a single spot and the other a cluster. Earlier conclusions that results were not in agreement with stability theory were based on identifying the (intermittency = 0.5) point with transition onset. The culprit in the disagreement is sub-transition, not stability theory.

Preceding Page Blank

The analysis predicts that heating becomes more attractive at lower Reynolds numbers and on plate-like bodies (i.e., those with blunter noses), because both encourage the singleton spot-wrapping scenario.

## HIGH LIFT LOW PRESSURE TURBINES

**H.P. Hodson and R.J. Howell**

University of Cambridge  
Whittle Laboratory  
Department of Engineering  
Cambridge, U.K.

In aircraft engines, chord-based Reynolds numbers of the order of  $0.5-5 \times 10^5$  are found in the low pressure turbines. Given that many component efficiencies are above 90 percent, improving the efficiency has become progressively more difficult. Consequently, a reduction in component count is now a common goal. Reducing the number of airfoils in a turbine inevitably leads to an increase in the blade loading. This increases the possibility of laminar separation in these low Reynolds number flows. Conventional (steady flow) wisdom dictates that the efficiency decreases as the laminar separation bubble grows. This perception has limited the development of low pressure turbines for many years.

In practice, the flow in turbomachines is unsteady due to the relative motion of the rows of blades. The combined effects of random (wake turbulence) and periodic disturbances (wake velocity defect and pressure fields) will affect the transition processes in low Reynolds number turbomachines. Research has shown that patches of transitional/turbulent flow can be created during the interaction of the upstream wakes with laminar boundary layers. These patches will reduce the efficiency. Fortunately, the so-called calmed regions, where the flow relaxes back to the laminar state, that follow the transitional/turbulent flow can withstand the deceleration much better than steady flow laminar boundary layers. Consequently, in high lift applications, attached laminar-like flow can be made to persist downstream of the steady flow laminar separation line, possibly as far back as the trailing edge. Most importantly, the calmed region represents an increase in efficiency as it is essentially laminar in nature and it is attached. Thus, there are two opposing mechanisms at work in the interactions between wakes and the boundary layers. As the frequency of wake-passing changes, so does the balance between these mechanisms.

This presentation will describe progress in understanding the details of the flow and the loss generation processes that arise in LP turbines. Particular emphasis will be placed on the unsteady separating flows, and how their effects may be exploited in controlling the laminar-turbulent transition processes that has allowed the successful development of ultra high lift low pressure turbines.

## **LOW PRESSURE TURBINE REYNOLDS NUMBER EFFECTS: SMALL ENGINE PERSPECTIVE**

**Greg Heitland**

Honeywell Engines and Systems  
Phoenix, AZ

The research work on low pressure turbine (LPT) performance lapse rate has been focused on the conditions for the large engine class size. This makes sense considering the majority of people travel via commercial airlines and the impact of additional fuel is directly felt on fares. The small engine class size that support business jet travel incur larger performance penalties due to the higher cruise altitude. Military high altitude applications, such as UCAV, result in LPT Reynolds number levels that are extremely low; the sturdiest turbine aerodynamicist will wobble at these operating conditions.

The turbomachinery industry carries a confusion factor when discussing Reynolds number; that is the length term. The classic boundary layer equations point to the use of surface length, for turbine airfoils the typical selection is the suction surface length. The suction surface length is what researchers tend to use for presentation of experimental/computational results. The various turbine engine companies use different length terms; axial chord, true chord, mean camber line length, and throat width. A review of available turbine rig tests shows Reynolds number variation data collapses best with the use of throat width. A blade row loss schematic is presented to support the use of throat width.

Boundary layer management methods, passive and active, are being developed to control low Reynolds loss in turbines. Honeywell has teamed up with University of Arizona and Arizona State University to research the low Reynolds issue based on a recent low pressure turbine airfoil design. A low speed cascade test rig with wake generator device will be used to collect the data, CFD modeling and enhanced near wall schemes will complement the rig data.

There are a several items that need to be addressed to close the gap between research and industry, two will be discussed here. One is the turbulence intensity level discrepancy between the test rigs and the actual engine environment. A second issue is the appropriate simulation of the upstream blade row wakes in cascade testing, the popular approach to date is cylindrical bars.

# **FREE STREAM UNSTEADINESS AND TURBULENCE— WHAT IS THE DIFFERENCE?**

**J. Hourmouziadis**

Jet Propulsion Laboratory, Aerospace Institute F1  
Berlin University of Technology  
Berlin, Germany

Boundary layer transition on the blading of turbomachinery is dominated by three phenomena:

- periodic unsteadiness
- high levels of free stream turbulence
- very often separated shear layers

The latter have been well known for several decades now and are usually accounted for empirically in design systems. Periodic unsteadiness has received increasing attention since the presentation of the investigations in the General Electric low speed compressor at the ASME Gas Turbine Conference 1995.

Working with unsteady boundary layers gives rise to a variety of questions concerning the physical understanding of the transition process. It even leads to doubts about traditional interpretations in steady flow. The following problems will be offered for discussion.

- Using an order of magnitude analytical approach, an amplitude-weighted Strouhal-no. is identified as a significant similarity parameter. Using this parameter and the Reynolds-no. a classification of unsteady flows is performed.
- Blade passing in turbomachinery and classical shear flows are classified in this framework.
- With the amplitude-weighted Strouhal-no. turbulence is resolved into a continuous spectrum of discrete frequency intervals. This model is used to classify the response of turbomachinery boundary layers using typical spectra from low speed and high speed full size experiments.

# NATURAL VERSUS BYPASS TRANSITION ON AXIAL COMPRESSOR BLADES— A NEED FOR REASSESSMENT?

G.J. Walker and J.D. Hughes\*

University of Tasmania

School of Engineering

Hobart, Australia

The transitional flow behavior on the outlet stator blades of a 1.5-stage axial compressor has been studied extensively using an array of surface hot film gauges covering both suction and pressure surfaces. Various techniques have been developed to identify flow regimes and individual events from fluctuations in quasi wall shear stress obtained from the surface gauges. Earlier work by Solomon and Walker was concerned with the evaluation of turbulent intermittency and the relaxation of flow following the passage of turbulent spots. The most recent studies by the present authors have involved the use of wavelet analysis to identify events characteristic of laminar instability waves.

Pitchwise average values of random inflow disturbance (free stream turbulence) experienced by the stator blades ranged from 2 to 3%, and ensemble average values were locally as high as 10% in passing rotor wakes. Despite these elevated free stream turbulence levels there was an almost universal evidence of instability wave amplification prior to turbulent breakdown in decelerating flow regions on the compressor blade. Although the two-dimensional wave amplification stage was apparently bypassed, there was no evidence for direct production of turbulent spots within the boundary layer supposed within the turbomachinery community to be characteristic of bypass transition. Unstable laminar flow regions up to 20% chord in length were observed on the compressor blade in these investigations, both in the path of turbulent strips induced by passing rotor blade wakes and in regions between these wake-induced transition paths in the time-chordwise position plane.

The signatures of individual instability wave events and their subsequent breakdown observed by the surface film gauges closely resembled those of wave packets in basic experiments on artificially generated spots arising from weak localised initial disturbances. The wave packet events showed evidence of amplification prior to breakdown. This observation provides further justification for use of the modified  $e^N$  method of predicting turbulent breakdown in natural transition, which was successfully applied by Solomon et al. (1999) in a quasi-steady manner to predict temporal fluctuations in transition onset on the compressor stator blades. Interestingly, the values of exponent  $N$  typically required for the compressor blade boundary layers were roughly comparable with those for the non-linear amplification stage in natural transition with a very low level of free stream turbulence.

Wave activity both occurred in and originated from the calmed region following the passage of a wake-induced turbulent strip on the compressor blade. This activity could have arisen either from the attendant wave packets that occur in adverse pressure gradients (as with artificially generated turbulent spots) or from the turbulent perturbations within the wake-induced turbulent strip itself. The more stable flow in the ensuing "calmed region" clearly did not guarantee the total absence of instability wave activity.

The length of transitional flow along an individual disturbance path was also observed to reach 20% of chord on the compressor stator. Thus the total length of blade surface over which the flow was governed by natural transition phenomena (either directly through wave packet amplification or indirectly through determining the dominant Tollmien-Schlichting wave frequency which governs the turbulent spot inception rate) was as much as 40% chord.

The presentation concludes by inviting discussion on the following points:

- the need for a more precise definition of the term "bypass" in relation to transition on turbomachine blades, and the need for greater consistency in definitions of bypass transition used by researchers in the turbomachinery and transition physics communities;
- the desirability of complementary transition studies in accelerating flow, where bypass phenomena should be relatively more important, and the efficacy of zero pressure gradient ("flat plate") studies which lie on the boundary of two significantly different regimes;
- remaining challenges for predicting turbulent breakdown on turbomachine blades.

**SEPARATION BUBBLE INTERACTIONS WITH TURBULENT SPOTS AND WAKES  
IN THE TURBOMACHINERY ENVIRONMENT AT  
REYNOLDS NUMBER OF AROUND 130,000**

**R.J. Howell and H.P. Hodson**

University of Cambridge  
Whittle Laboratory  
Cambridge, U.K.

This paper describes the details of the interactions of individual turbulent spots, their calmed regions and separation bubbles.

Many hot wire and film measurements have shown that wakes cause turbulent spots to form in the boundary layer at the approximate position where flow separation would normally occur with steady inflow. Artificially generated individual turbulent spots were created just before flow separation on a flat plate with imposed turbine pressure distribution. This caused the (normally) separated boundary layer to reattach to the blade surface. A large number of detailed unsteady measurements were taken to show how the velocity profiles of a separation bubble were affected by the passage of turbulent spots and their calmed regions. Other experiments also included the effects of wakes.

These measurements showed that initially, the inner part of the separation bubble was reattached by the presence of a turbulent spot, while the outer half of the velocity profile remained unaffected. Only when 50% of the length of the spot had reached the separation location, did any changes occur in the outer half of the separation bubble. The spot seems to act like a wedge travelling under the separation bubble at first and as the rest of the spot reaches the separation location, the higher regions of what was the separation bubble are then affected. During this process there is a reduction in shape factor from 3.4 to 1.6. As the calmed region passed by, the flow gradually relaxed back to a separated boundary layer. At the trailing edge of the flat plate, the effects of the calmed region were present for up to three times the duration of the turbulent part of the spot.

# **VISUALIZATION OF TRANSITIONAL HEAT FLUX IN THE PRESENCE OF FREESTREAM TURBULENCE AND PRESSURE GRADIENT**

**T.V. Jones and R.J. Anthony**

University of Oxford  
Department of Engineering Science  
Oxford, U.K.

**J.E. LaGraff**

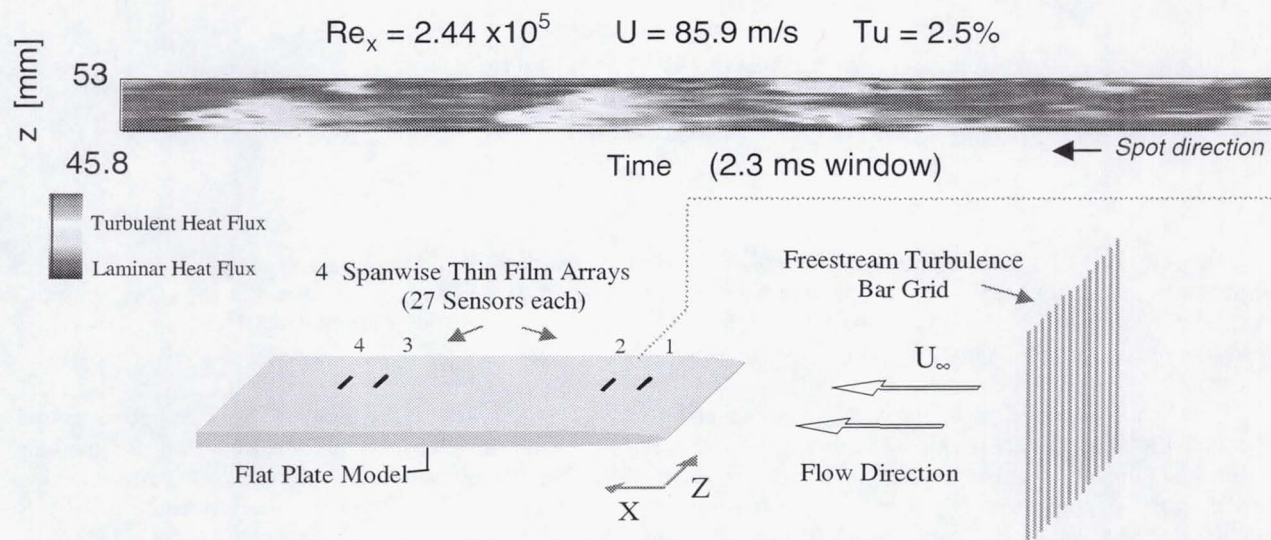

Syracuse University  
Department of Mechanical, Aerospace, and Manufacturing Engineering  
Syracuse, NY

Optimum design of gas turbine blades depends on accurate prediction of boundary layer transition. The purpose of this research is to obtain more information on the generation, propagation, and coalescence of turbulent spots in a transitional boundary layer, including the effects of freestream turbulence, favourable and adverse pressure gradients, and spanwise acceleration.

Turbulent spot heat flux images are obtained using high-density thin film heat transfer gauge arrays developed especially for this study. The non-intrusive sensor arrays allow high frequency (up to 200 kHz), high spatial resolution (0.2 mm) surface heat flux measurements to be made. Figure 1 illustrates their use on a flat plate wind tunnel model. Experiments are run in a subsonic wind tunnel at Oxford over a range of Reynolds number and Mach number (0.1-0.4). Surface heat flux is driven by a temperature difference between the model and freestream airflow.

Experimental results clearly show increasing freestream turbulence intensity  $Tu$  significantly increases turbulent spot generation rate. At higher levels of freestream turbulence, most of the heat transfer fluctuations are caused by freestream eddies entering deep into the boundary layer. Favorable pressure gradient lengthens the transition region, while adverse pressure gradient hastens instability and can easily lead to abrupt separated flow transition. There also appear to be fundamental differences between the dynamics of bypass 'spots' or streaks, and natural spots. For example, individual bypass 'spots' do not appear to grow as much as natural spots in accelerating flow.

High frequency measurements with spanwise detail enable direct measurement of turbulent spot generation rate, spot size, and spot/streak shapes. The imaging capability presented may allow us to "see" a few more pieces of the transition "puzzle" that we have not been able to see clearly before. New data such as this may lead to a better understanding of boundary layer transition in complex flows.

**Figure 1** Experimental setup showing the flat plate wind tunnel model instrumented with high-density thin film arrays. The spanwise arrays shown are perpendicular to the flow direction. The top image is a view of transitional heat flux in the  $z$ - $t$  plane from array #2 which shows the heat flux events crossing a 7.2 mm span in less than 2.3 ms. The high frequency, high spatial resolution measurements can capture turbulent spot detail in a high speed transitional boundary layer.

# THE INITIATION AND DEVELOPMENT OF TURBULENT SPOTS

**Mark W. Johnson**

University of Liverpool  
Department of Mechanical Engineering  
Liverpool, U.K.

The turbulent spot can be considered as the 'building block' of a transitional boundary layer flow. The appearance of the first turbulent spots defines the start of transition location and the rate at which the spots grow and merge determines the transition length. A better understanding of how spots are initiated and develop can therefore lead to more accurate prediction in the transition process.

Work over the past few years (Johnson and Ercan [1999], Mayle and Schultz [1997] and Roache and Brierley [2000]), has shown that freestream turbulence leads to the development of low frequency fluctuations within the laminar boundary layer, which grow in amplitude as the boundary layer develops. For bypass transition this growth is approximately linear with streamwise distance, but in the case of natural transition the growth is supplemented through the exponential growth in Tollmien-Schlichting frequencies once the stability limit is reached. The laminar fluctuations eventually reach a critical amplitude which is sufficient to initiate turbulent spots. The author has previously developed a simple model which suggests that a turbulent spot is initiated each time the near wall local velocity drops below 50% of its mean value and that this criterion leads to a transient separation of the flow due to the onset of a local instability. In the present work, new statistical data derived from hot wire signals measured in the near wall region of pre-transitional boundary layers is shown to support this model. The rate at which threshold events are observed in the experiment also correlates with the observed spot production rate.

The structure of turbulent spots has been studied numerically using a linear perturbation procedure. The results show that, once a transient separation point is formed, it moves downstream below the trailing edge of the developing turbulent spot and hence moves with the spot trailing edge velocity of approximately 50% of that of the freestream. The fluid motion within the spot can be usefully interpreted from the point of view of an observer travelling with this velocity. In a laminar flow, this observer will see two streams of fluid. The first stream, consists of fluid close to the wall ( $u/U < 0.5$ ) which will approach the observer from downstream. The second stream is formed from fluid further from the wall which will approach him from upstream. Once the spot is formed the first stream is lifted from the surface around the hairpin vortex, which exists at the tail of the spot, and is accelerated forwards into the spot to move downstream away from the observer. The second stream drops towards the surface, to fill the space vacated by the first stream, before bifurcating behind the spot. The lower bifurcation branch approaches the wall behind the separation point such that the resulting increase in skin friction decelerates the flow so that it moves, relative to the observer, back upstream to form the calmed region. The upper bifurcation branch moves over the top of the hairpin vortex to mix out with the first stream within the spot. A number of flow visualisation movies created from the calculation results have been used to interpret the details of the flow structure. Numerical information on the extent and shape of the spot and calmed region have also been used to create correlation equations for spot propagation parameters as functions of streamwise pressure gradient and boundary layer Reynolds number.

## ON THE DYNAMICS OF THE CALMED REGION BEHIND A TURBULENT SPOT

**O.N. Ramesh\* and H.P. Hodson**

University of Cambridge  
Whittle Laboratory  
Department of Engineering  
Cambridge, U.K.

The calmed region behind a spot is the focus of this study. Here, a simple two-dimensional analysis is done in order to study the dynamics of the calmed region. By considering the near wall dynamics of the calmed region in an Eulerian sense, by neglecting advection and turbulent stress terms in the streamwise momentum equation, an expression for the time variation of the skin friction is obtained. This expression bears out the intuitive expectation that the skin friction at a location decays exponentially to the laminar value after the passage of a turbulent spot. This seems to be the case irrespective of the mean pressure gradient as long as the flow remains attached. Furthermore, it also suggests a way of plotting the skin friction variation with time for different pressure gradients so that all of them could be collapsed onto a single curve.

For calmed regions in a constant pressure flow, the variation of integral parameters and the duration of the calmed zone can be estimated by solving the unsteady momentum integral equation. The expression obtained for the duration is roughly in accord with the form suggested by a crude order of magnitude analysis of the momentum equation.

More importantly, it is shown that the benign aspects of the calmed region such as stability to infinitesimal disturbances could be explained heuristically. By considering the equation for near-wall dynamics for a constant pressure flow, it could be seen that the vorticity profile in the calmed region is qualitatively similar to that of a steady favourable pressure gradient flow and hence stable; the role of pressure gradient in the steady flow being similar to that of the unsteady term in the calmed zone. If there is a mean pressure gradient in the flow, it will add to the unsteady term thereby modifying the vorticity profile and hence the stability characteristics of the calmed zone.

A detailed experimental investigation was carried out to study the process of boundary layer transition induced by a bar generated wake travelling over a laminar boundary layer on a flat plate. Wake-induced transition is believed to take place via discrete turbulent spots and an encapsulated cholesteric liquid crystals coating has been employed on a heated flat plate to reveal detailed information over the full surface. The information includes the thermal characteristics, the spot onset locations in time and space and the spot formation rate. The results are also compared to intermittency plots and time-distance diagrams obtained by using surface-mounted thin film gauges. The data are also compared to well established correlations and other published data from the literature for existing wake-induced transition models. It is found that the onset is distributed beneath the trajectory of the wake.

## THE NASA LOW-PRESSURE TURBINE FLOW PHYSICS PROGRAM—A REVIEW

**David E. Ashpis**

National Aeronautics and Space Administration  
Glenn Research Center  
Cleveland, OH

An overview of the NASA Glenn Low-Pressure Turbine (LPT) Flow Physics Program will be presented. The flow in the LPT is unique for the gas turbine. It is characterized by low Reynolds number and high freestream turbulence intensity and is dominated by interplay of three basic mechanisms: transition, separation and wake interaction. The flow of most interest is on the suction surface, where large losses are generated due to separation.

The LPT is a large, multistage, heavy, jet engine component that suffers efficiency degradation between takeoff and cruise conditions due to decrease in Reynolds number with altitude. The performance penalty is around 2 points for large commercial bypass engines and as much as 7 points for small, high cruise altitude, military engines. The gas-turbine industry is very interested in improving the performance of the LPT and in reducing its weight, part count and cost. Many improvements can be accomplished by improved airfoil design, mainly by increasing the airfoil loading that can yield reduction of airfoils and improved performance. In addition, there is a strong interest in reducing the design cycle time and cost. Key enablers of the needed improvements are computational tools that can accurately predict LPT flows. Current CFD tools in use cannot yet satisfactorily predict the unsteady, transitional and separated flow in the LPT. The main reasons are inadequate transition & turbulence models and incomplete understanding of the LPT flow physics.

NASA Glenn has established its LPT program to answer these needs. The main goal of the program is to develop and assess models for unsteady CFD of LPT flows. An approach that consists of complementing and augmenting experimental and computational work elements has been adopted. The work is performed in-house and by several academic institutions, in cooperation and interaction with industry. The program was reviewed at the Minnowbrook II meeting in 1997. This review will summarize the progress that was made since and will introduce newly started projects.

The LPT program is focused on three areas: acquisition of experimental and numerical databases and on modeling and computation. Priority was initially given to experiments. There are three classes of experiments: simulated LPT passages, linear cascade, both with and without wakes, and low-speed rotating rig. They are being conducted as follows: At NASA GRC on a flat surface with blade pressure distribution, at the US Naval Academy on a curved surface. The addition of wakes is studied at the University of Minnesota in a curved passage with a retractable wake generator, and at Texas A&M University in a linear cascade with continuously running wake generator. The pressure distribution of the Pratt & Whitney blade "Pak B" is used in all these experiments. Experiments have been performed also in the GEAE Low-Speed Rotating Turbine (LSRT) rig with GE-designed airfoils. Work on numerically generated database is in progress at the University of Kentucky, using the DNS/LES code LESTool developed there. Turbulence/transition model assessment and development is performed also at the University of Kentucky, where a new intermittency transport model was developed and many experimental test cases have been numerically computed. Assessments of models using simulations of multistage LPT experiments were performed at Virginia Commonwealth University using the Corsair code. Work on suction surface separation delay, using passive and active flow-control, has also been initiated. Following the overview, Principal Investigators attending the workshop will present in detail several of the projects supported by NASA.

# **PREDICTIONS OF TRANSITIONAL FLOWS IN A LOW PRESSURE TURBINE USING AN INTERMITTENCY TRANSPORT EQUATION**

**Y.B. Suzen, G. Xiong, and P.G. Huang**

University of Kentucky  
Department of Mechanical Engineering  
Lexington, KY

A new transport equation for the intermittency factor is presented to predict the transitional flows in low-pressure turbine applications. The intermittent behavior of the transitional flows is taken into account and incorporated into the computations by modifying the eddy-viscosity,  $\mu_t$ , with the intermittency factor,  $\gamma$ . Turbulent quantities are predicted by using Menter's two-equation turbulence model (SST) and the intermittency factor is obtained from the solution of a recently developed transport equation model. The new transport equation model not only can reproduce the experimentally observed streamwise variation of the intermittency in the transition zone, but it also provides a realistic cross-stream variation of the intermittency profile.

The new model is applied to predictions of a modern low-pressure turbine experiment and detailed comparisons of the computational results with the experimental data are presented. The new model has been shown to be capable of predicting the low-pressure turbine flow transition under a variety of Reynolds number and freestream turbulence conditions.

## ERCOFTAC TRANSITION MODELLING SPECIAL INTEREST GROUP

### THEMATIC NETWORK TRANSPRETURB: TRANSITION PREDICTION METHODS FOR TURBOMACHINERY AND OTHER AERODYNAMIC FLOWS

Erik Dick

Ghent University

Department of Flow, Heat, and Combustion Mechanics

Gent, Belgium

The interest group and thematic network have 25 participating research groups from universities, research institutes and industry. There are 5 subgroups: "Intermittency and Simple Model Approaches" studies intermittency concept based methods and integral methods; "Eddy Viscosity Models" studies two-equation approaches, including non-linear extensions like NLEVM and EARS; "Reynolds Stress Transport Models"; "Transition Simulation" mainly uses LES as analysis tool and as means to create numerical data bases; "Experimental Data", aims at near-reality test cases, both steady and unsteady. The thematic network receives EC funding for the period September 1998 to August 2001. The thematic network has as objective to come to models for bypass transition which can be used in everyday industrial practice. The industrial partners insist on methods with sufficient generality but without much complexity. This implies that integral methods are considered as not general enough and that approaches based on conditionally averaged equations and approaches using RSM are seen as too complex. The technique preferred by the industrial partners is two-equation turbulence models ( $k-\epsilon$  and  $k-\omega$  types, two-layer types), with or without non-linear extensions, complemented with an intermittency transport equation. As a consequence of this industrial preference, in practice there is no strict distinction between the activities of the subgroups 1,2 and 3. Subgroups 2 and 3 have formally merged and some partners are active in different subgroups.

For the development of models, it was agreed to use a sequence of test cases with increasing complexity: T3L, semi-circular leading edge (Rolls-Royce data), to be used by all partners working on modelling, especially T3L1 (0.2 % fst) and T3L3 (3% fst); further, to be used by as many partners as appropriate: T3H, flat plate with heat transfer, 5% fst (Kiev data); T3K, linear turbine cascade (Ercoftac Turbomachinery Sig data); T3K (Durham), T3K+(Lyon); T106, unsteady turbine cascade (Cambridge data); IGV-rotor-stator (Tasmania data). Additionally, Subgroup 1 uses VKI linear turbine cascade data. Subgroups 2 and 3 use DNS data for laminar separation bubble induced transition, DNS data for oscillating flat plate boundary layer, DNS data for wake passing transition, all three data from Stanford. Subgroup 4 works at LES simulations of the cases T3L and T106 with and without wake passage (Surrey). Fundamental DNS simulations have been done (Stockholm). Subgroup 5 works at experiments on a steam turbine IGV/rotor (Genua), a steam turbine rotor/stator (Czestochowa), a multi-stage compressor (Cranfield). Experimental work on T3L with and without wake passage (Thessaloniki and Brussels) is finished at this moment.

Some industrial partners (Rolls-Royce, Alstom) have up to now been concentrating on validating their existing codes for T3L and T3K, often with a rough transition model, typically based on Abu-Ghannam and Shaw correlations with turbulence shut off upstream of transition. Other industrial partners (BMW-RR, KEMA) implement a specific model (Dresden and Delft). TU.Delft, Umist and U.Thessaloniki work on RSM and  $k-\epsilon$  models without use of an intermittency equation. Some successful results were obtained. AEA, U.Roma3, U. Gent, Institute of Thermomechanics Prague and U. Cambridge work at  $k-\epsilon$  and  $k-\omega$  types linked with an intermittency transport equation. The most encouraging results up to now have been obtained by U. Cambridge with a two equation  $k-\epsilon$  model and the intermittency equation coming from the SLY-RSM or a prescribed intermittency method. U. Leicester and U. Liverpool work at fundamental experiments and simulations of the behaviour of turbulent spots with the aim to improve intermittency correlations or intermittency equations. The Institute of Thermomechanics Prague works with the same aim on fundamental experiments on the effect of the turbulence length scale on transition.

# MODELLING OF BY-PASS TRANSITION BY MEANS OF A TURBULENCE WEIGHTING FACTOR

**J. Steelant**

European Space Research and Technology Centre (ESTEC)  
Noordwijk, The Netherlands

**E. Dick**

Ghent University  
Department of Flow, Heat, and Combustion Mechanics  
Gent, Belgium

In contrast to natural transition which emanates from the breakdown of amplified disturbances within the boundary layer, by-pass transition is caused by the free-stream turbulence affecting the pre-transitional (pseudo-laminar) layer directly by diffusion and indirectly by pressure fluctuations. If the free-stream turbulence is high enough, i.e.  $Tu \geq 1\%$ , the transition happens far further upstream than what would be expected for natural transition. Also the transition length is shorter and is directly related to the turbulence level.

The diffusion of turbulent eddies into the boundary layer prior to the transition onset has an intermittent character and is first localized in the outer part of the laminar boundary layer. Intermittent behaviour is also seen during the transition where the flow in the boundary layer is characterized by distinct turbulent and laminar phases alternating in function of time. The intermittent behaviour during transition has been quantified by the intermittency factor  $\gamma$ . This factor is the relative fraction of time during which the flow is turbulent at a certain position. It evolves from 0% at the transition point up to 100% at the end of transition.

The same relative fraction of time can be taken to quantify the intermittent behaviour of the diffusing turbulent eddies in the pseudo-laminar boundary layer. This parameter, named here as freestream factor  $\omega$ , is 0% near the wall and tends to 100% in the freestream.

In intermittently changing flows, global time averages commonly used in classical turbulence modelling are not valid anymore. To describe the transitional zone and the outer layer zone, it is necessary to use conditional time averaging. These averages are taken during the fraction of time the flow is laminar or turbulent respectively. As we are only interested in the state of the flow, i.e. laminar or turbulent, at a certain position, it is sufficient to use a turbulence weighting factor  $\tau(x, y)$ , which is the sum of the intermittency factor  $\gamma(x, y)$  and the freestream factor  $\omega(x, y)$ :  $\tau(x, y) = \gamma(x, y) + \omega(x, y)$ . As a consequence, this factor  $\tau$  incorporates two effects: firstly the diffusion of freestream turbulent eddies into the boundary layer and secondly the transport and growth of the turbulent spots during transition. Hence, this factor is 0% in the vicinity of the wall within the pretransitional boundary layer, and 100% in the freestream and inside a fully turbulent boundary layer.

To evaluate the two-dimensional  $\tau$ -value in the computational field, a transport equation is derived [1]:

$$\frac{\partial \bar{\rho} \bar{u} \tau}{\partial x} + \frac{\partial \bar{\rho} \bar{v} \tau}{\partial y} = \frac{\partial}{\partial x_i} \left[ \mu_\tau \frac{\partial \tau}{\partial x_i} \right] + P_\tau - C_3 \mu_\tau \frac{\tilde{c}}{\tilde{c}_\infty^2} \frac{\partial \tilde{c}}{\partial n} \frac{\partial \tau}{\partial n},$$

which also accounts for the effects of turbulence intensity, pressure gradient and compressibility on the spot growth rate. The wall-value of  $\tau$  is set to zero only at the wall prior to transition onset. The latter is described by a correlation [1]. This transport model in combination with the conditioned Navier-Stokes equations [2] has been validated with success on both flat plates and turbine cascades.

## TOWARD DIRECT NUMERICAL SIMULATIONS OF TURBINE FLOWS

**Thorwald Herbert**

Ohio State University

Department of Mechanical Engineering

Columbus, OH

In spite of partial success, we have halted our attempt to analyze transition in turbine boundary layers by studying the stability of an initially laminar flow because the rise of turbulence seems to be associated with unacceptable changes of the core flow. Instead, we have adopted the conclusion of the last meeting and worked toward the direct simulation of realistic flows in turbines to obtain insight into the structure of turbulence and heat transfer. Estimates show that, in spite of a patchy turbulent core flow, the buffeted boundary layer may go through transition, but the time of travel through the passage may be insufficient, the change in local conditions too rapid, and periodic unsteadiness too severe to establish the mature "textbook turbulence" underlying common turbulence models.

The large scale of the computational task requires distributing the work load over a group of computers. Different basic equations (e.g. for fluid flow and heat conduction) may need to be solved in adjacent domains. Moreover, the results of the unsteady computation cannot be saved and analysis of the data must be performed simultaneously with the computation. To address these and other requirements, we have designed and developed major components of DICE - a Distributed Interactive Computing Environment. On the highest level, DICE consists of a framework void of any physical problems or numerics. This framework executes any number of addressable modules on prescribed or internally chosen hosts on a heterogeneous computer network, typically a network of workstations under Unix, Linux, or Windows NT. These modules can be computational solvers for a given set of equations in one block of the physical domain, modules for visualization or plotting, graphical user interfaces for controlling the code or the visualization, analysis modules, print module, file manager, or an archive for collecting selected data. Integration of data production and analysis is key to the task at hand. Modules communicate by a command language that is compact, easy to read, use, and extend. Every module includes a minimum set of objects to interpret certain parts of the command language, communication routines, and the capability to start the whole system (which enables developing and debugging new modules locally).

The code receives input commands from a file stack, standard input, graphical user interface, an interactive viewing window, or from a module that imports data from CAD/CAM systems or Plot3D files. Graphical interface and viewing window can be used to draft or edit the geometry, to assign materials, equations, or parameters, to decompose the physical domain into blocks, to assign grid sizes, or to change the point distributions along boundaries or within a block. Routines for different types of grid generation are an integral part of the viewing windows and the numerical solvers. All objects are embedded in a hierarchy and offer a standard set of operations. For example, every object is capable of sending its

status across the network or to a file, enabling scripting and full restart capabilities for both computational solvers and other modules by performing one send operation on the highest level.

The code is written in C++ and is driven by events. The asynchronous operation of the code components under PVM is coordinated by a central hub. Every computational solver is able to initialize or restart grid generation or computation in some block of the physical domain, to perform a given number of time steps, to receive data from the network, and to send selected data to a given destination. The integration of grid generation and computation provides for adaptive grids, moving interfaces, and inspection/correction of the grid quality. The current version of the code is restricted to structured grids (transfinite, control-net, or elliptic). So far the code solves the heat conduction equation, incompressible Navier-Stokes equations, full potential equation, and provides for gas-liquid and liquid-solid interfaces. Second-order and higher-order methods with optional multigrid acceleration have been implemented. Within a special C++ framework and coding scheme, implementation and verification of new or modified equations is usually a matter of days.

There are still many loose ends to be tied up, and ongoing efforts aim at improving the numerical solvers and the quality of the data transferred between blocks with different grids and relative motion. The available basis, however, has proven versatile and capable of making many dreams of large-scale computation come true.

# EXPERIMENTAL INVESTIGATION OF TRANSITION TO TURBULENCE UNDER LOW-PRESSURE TURBINE CONDITIONS: MEASUREMENTS WITH AND WITHOUT WAKES

Terrence W. Simon, Richard W. Kaszeta, Kebiao Yuan, and Federico Ottaviani

University of Minnesota  
Heat Transfer Laboratory  
Department of Mechanical Engineering  
Minneapolis, MN

This research was designed to address a need for detailed experimental data which document transition in boundary layers and separated flows over highly-loaded airfoils, including the effects of passing wakes. The program objectives are accomplished with the following steps:

First, the effects of freestream turbulence and Reynolds number are documented without wakes in a facility which simulates the flow through a modern, highly-loaded, low-pressure turbine.

Next, this case is repeated, but with the influence of simple, rod-generated wakes added. By comparing, we can identify the effects of wakes on transition in the boundary layer.

We have completed the first part, Qiu and Simon (1997) and Simon et al. (2000). It shows cases with strong separation at low Reynolds numbers and low turbulence levels and cases with much smaller separation bubbles with higher Reynolds number or freestream turbulence. It shows also that a correlation for the streamwise distance from separation to the start of transition by Davis et al. (1985) is quite accurate and that a model for the intermittency path by Dhawan and Narasimha (1958) is remarkably good, in spite of its derivation from attached boundary layer flow transition data. A need for better prediction of the transition length is indicated, however.

Early results of the with-wake data were presented and comparisons were made to the no-wake study. Wakes are generated by sliding a rack of rods through the approach flow tunnel. A photogate was used to verify that the wake generator sled is moving at a uniform velocity when measurements of the flow are made. To characterize the wakes, 100 separate traverses of the sled were made and an ensemble average of 100 separate traverses of each rod was generated. We see that the minimum velocity at the center of the wake is approximately 85% of the average value, which matches the work of (Halstead et al, 1995) who used a rotating airfoil stage (simulating a rotating turbine stage) to create wake profiles, but the turbulence intensity peaks at 15%, more than twice that reported by Halstead. This may be consistent with Halstead's assertion that rods seem to produce more turbulence than airfoils of the same loss coefficient. It should be noted, however, that flow over the airfoils of the Halstead study was not strongly separated and a highly-loaded airfoil, such as that of the present study (Pak B), will be inclined to separate more strongly.

The unsteady boundary layer measurements include the ensemble-averaged, period-resolved profiles of velocity, rms velocity fluctuation and intermittency over the surface. Characterization of this flow will demonstrate the influence of the passing wake on the state of the boundary layer or separated flow zone, including the "calming" region (Halstead et al, 1995). Further, such data will allow testing of transition models which have been developed to incorporate the effects of passing wakes on transition.

# **DIRECT SIMULATION OF UNSTEADY WAKES AND TRANSITION IN A TURBINE PASSAGE**

**P.A. Durbin and X. Wu**

Stanford University  
Department of Mechanical Engineering  
Stanford University, CA

Direct numerical simulations have been performed of unsteady wake effects and of transition on a flat plate and in a turbine passage. Passing wakes were simulated by sweeping a self-similar, turbulent wake across the entrance to the computational domain. Computations were performed on a highly parallel computer with on the order of 50million grid points. The geometry and flow conditions of the turbine passage correspond to the 'T106' blade being studied in a number of laboratory experiments.

Flat plate, zero pressure gradient bypass transition occurs through four stages. In the first, elongated regions of high or low velocity form near the wall. Secondly, the low velocity regions lift from the surface, producing a lifted, backward jet. *This provides a receptivity path for external turbulence to enter the boundary layer*; the third stage is an instability of the lifted jet. In the final stage the instability cascades to small scale, locally filling the boundary layer with a turbulent spot. At this stage transition to turbulence has occurred, although the spots subsequently evolve and merge to produce a fully turbulent boundary layer.

A second set of simulations addresses the development of wakes in a low pressure turbine passage. New vortical structures were observed to evolve within the wake as it traversed the passage. They were produced by interaction between the wake and the mean straining field. An intriguing asymmetry was observed between the suction and pressure sides of the passage. It can be explained by the relative orientation of the wake and rate of strain. Streamwise elongated vortices descend from the passage and lie along the pressure surface. Secondary vortices are caused by the viscous boundary condition, leading to a set of surface vortices. Three-dimensional, small scale turbulence is amplified near the suction side. The unsteady, asymmetric, vortical field will be illustrated and discussed for its relevance *to predicting turbulence and transition in turbines*.

Transition via spots occurs on the suction surface toward the rear edge. Some evidence was seen that in the absence of passing wakes more orderly transition occurs in the adverse pressure gradient region right before the trailing edge.

## UNSTEADY STATOR-ROW FLOW WITH WAKE PASSINGS

Frank T. Smith and Linzhong Li

University College

Department of Mathematics

London, U.K.

This ongoing work is aimed primarily at the understanding and modelling of the unsteady flow through a vertical periodic row (stack) of stationary quasi-stator blades, as affected by the wakes from a row of quasi-rotor blades upstream which are also vertically periodic but moving downward.

The periodic wake itself is first found to generate a pressure drop ahead of the stator row.

The subsequent unsteady motion within the stator row is taken to be two-dimensional and to be periodic in the vertical co-ordinate, to allow for the blade to blade interactions. This is accompanied, in a first shot, by an assumption of thin-layer and slowly-varying behaviour in order to capture the global properties of the stator motion via rapid numerical sweeps, as far as possible in a forward-marching manner.

The global properties include substantial regions of adverse pressure gradient over the rear of the typical blade and almost steady separations which periodically (in time) are made unsteady by the passage of the wakes. The wakes and the stator motions can be computed together, allowing for the interactive rows.

As a second shot, the influences of non-slow behaviour are incorporated in the overall approach by means of temporal or spatial lagging of their effects, for example through the normal pressure gradients, again in an attempt to keep the global numerical sweeps as rapid as possible. The effects of the typical wake thickness, the Reynolds number and the temporal period have been studied, among other main features. The above theory and computation is for laminar incompressible flow but should be extendable to turbulent and compressible flow also.

The consequent development of spots initially localised and at low amplitudes is described in allied papers, particularly in the regions of adverse pressure gradient or flow reversal generated on the blade as above. The effects of vortical wake passing as an initiator, followed by nonlinear evolution, nonparallel flow evolution and the three-dimensional responses are included in the spot analysis.

## RELAXATION FOLLOWING WAKE IMPINGEMENT ON REATTACHING FLOW

J.P. Gostelow, N.M. Allen, A. D'Ovidio, and J.A. Harkins

University of Leicester  
Department of Engineering  
Leicester, U.K.

Experiments are in progress aimed at direct comparisons between triggered turbulent spots and wake-induced turbulent patches on a flat plate in a low-speed wind tunnel. These are being conducted under strong adverse pressure gradients giving alternative conditions of a long laminar separation bubble, an incipient laminar separation and an early natural transition, as determined by small changes in free-stream Reynolds number. Good progress has been made on the experiments involving triggered spots and work has commenced on wake-induced turbulent patches.

The purpose is to gain an appreciation of turbulent spot behavior under an adverse pressure gradient as a foundation for the improved modeling of wake-induced turbulent patches in predictions of transitional boundary layer flows on axial turbomachine blading.

A substantial experimental program on triggered spots has now been completed for the long separation bubble and incipient laminar separation cases. This will give two new points which broadly confirm the existing Solomon, Walker, Gostelow spot-spreading correlation for transition length.

Preliminary boundary layer traverses are presented for the case involving wake impingement on the reattachment region of a laminar separation bubble. These show the similarity between the wake interaction and the triggered turbulent spot and also the strong effect of the calmed region behind the wake interaction. The calmed region prevails behind any such disturbance whether two-dimensional or three-dimensional. Unsteady transition phenomena occurring as a result of wake interaction events on compressor and turbine blading are consistent with the behavior of triggered turbulent spots on a flat plate. Experiments on turbulent spots are directly applicable to the complex flows on compressor and turbine blading. The overall effect of the wake interaction, and the resulting calmed region, is to delay the transition process and to stabilize the boundary layer against separation.

The velocity profiles show that within the impinging wake, the rms disturbance level is strong but there is little velocity perturbation from the incoming laminar layer profile. The turbulent patch behind the wake is more characteristic of a turbulent layer and shows a strong velocity perturbation from the laminar layer velocity profile. The calmed region is strong and has a more stable velocity profile than a steady laminar boundary layer under the same local pressure gradient; the amplitude of Tollmien-Schlichting (T-S) instabilities is therefore temporarily reduced and the progression to harmonic breakdown and turbulence delayed. Turbulence from the surrounding boundary layer eventually contaminates the region leading to its destruction, but this process may be quite protracted. Because of its increased wall shear stress the calmed region flow is also more resistant to separation, and this may have beneficial consequences for stall margin.

Similarities have been investigated between transition through spots on a flat plate and wake-induced turbulent patches on turbine and compressor blades. In triggered spots on a flat plate transition proceeds by natural growth; small disturbance, to wave packet, to developed spot. Flat plates, turbine cascades and rotating compressor all show natural transition with strong amplification of T-S waves. Harmonic development to turbulence then develops. The instabilities are amplified by strong adverse pressure gradients.

## LEADING-EDGE RECEPTIVITY TO VORTICAL DISTURBANCES

**Thomas C. Corke and Ercan Erturk**

University of Notre Dame  
Aerospace and Mechanical Engineering Department

The amplitude response of Klebanoff modes near the leading edge of a flat plate was studied for different amplitudes and scales of free-stream turbulence. The leading edge geometry consisted of 6:1 and 12:1 ellipses which were matched to a flat plate. The free-stream turbulence conditions were set using perforated grids and screens with different hole and mesh sizes. These were carefully selected so that combinations of turbulence intensities and scales could be independently changed. The free-stream turbulence conditions were documented for the grids and screens in terms of the total r.m.s, and spectra of streamwise velocity fluctuations. The turbulence conditions at the leading edge were changed by placing the plate at different streamwise distances from the grid or screen. The response of the boundary layer near the leading edge was then measured through wall-normal profiles of the mean and r.m.s. velocity fluctuations. The r.m.s. distributions and streamwise development agreed well with those associated with the Klebanoff mode. These were then used to determine an input-output response of the Klebanoff mode amplitude with the free-stream turbulence level. The results showed two regions: a 2:1 amplitude response for  $u'/U_\infty \leq 0.5\%$  and a 4:1 response when  $u'/U_\infty > 0.5\%$ . In both cases, the response appeared to be linear.

# EXPERIMENTAL INVESTIGATION OF SEPARATED AND TRANSITIONAL BOUNDARY LAYERS UNDER LOW-PRESSURE TURBINE AIRFOIL CONDITIONS

**Lennart S. Hultgren**

National Aeronautics and Space Administration  
Glenn Research Center  
Cleveland, OH

**Ralph J. Volino**

United States Naval Academy  
Department of Mechanical Engineering  
Annapolis, MD

Modern low-pressure turbine airfoils are subject to increasingly stronger pressure gradients as designers impose higher loading in an effort to improve efficiency and to reduce part count. The adverse pressure gradients on the suction side of these airfoils can lead to boundary-layer separation, particularly under cruise conditions. Separation bubbles, notably those which fail to reattach, can result in a significant degradation of engine efficiency.<sup>1,2,3</sup> Accurate prediction of separation and reattachment is hence crucial to improved turbine design. This requires an improved understanding of the transition flow physics. Transition may begin before or after separation, depending on the Reynolds number and other flow conditions, has a strong influence on subsequent reattachment, and may even eliminate separation. Further complicating the problem are the high free-stream turbulence levels in a real engine environment, the strong pressure gradients along the airfoils, the curvature of the airfoils, and the unsteadiness associated with wake passing from upstream stages. Because of the complicated flow situation, transition in these devices can take many paths that can coexist, vary in importance, and possibly also interact, at different locations and instances in time.

The present work was carried out in an attempt to systematically sort out some of these issues. Detailed velocity measurements were made along a flat plate subject to the same nominal dimensionless pressure gradient as the suction side of a modern low-pressure turbine airfoil ('Pak-B'). The Reynolds number based on wetted plate length and nominal exit velocity,  $Re$ , was varied from 50,000 to 300,000, covering cruise to takeoff conditions. Low, 0.2%, and high, 7%, inlet free-stream turbulence intensities were set using passive grids. These turbulence levels correspond to about 0.2% and 2.5% turbulence intensity in the test section when normalized with the exit velocity. The Reynolds number and free-stream turbulence level do not have a significant effect on the location of boundary-layer separation unless they are high enough to induce transition upstream of separation. The location and extent of the transition zone, in contrast, depend strongly on  $Re$  and TI. The beginning of reattachment closely follows the onset of transition. Under low free-stream turbulence conditions the boundary layer is laminar at separation and then begins to exhibit fluctuations in a finite frequency band in the shear layer over the separation bubble. These fluctuations are due to instability waves. The fluctuations grow in magnitude, higher harmonics are generated, and finally lead to a breakdown to turbulence. Transition begins in the shear layer, but quickly spreads to the near wall region and causes the boundary layer to reattach. The transition is rapid and the resulting turbulence contains a full range of high and low frequencies. Under high free-stream turbulence conditions, slowly growing low-frequency fluctuations are induced in the pre-transitional boundary layer by the free-stream.<sup>4,5,6</sup> The separation bubbles are considerably thinner than in the low TI cases, resulting in thinner boundary layers at the end of the test wall. At  $Re=50,000$  and  $100,000$ , the pre-transitional boundary layer separates at about the same location as in the low TI cases. Transition occurs through a bypass<sup>7</sup> mode, begins upstream of the corresponding low-TI location, and proceeds in a manner similar to that of an attached boundary layer. Under high TI at  $Re=200,000$  and  $300,000$ , transition begins before separation. The boundary layer may separate, but if it does the separation bubble is very short and does not significantly affect the downstream development of the boundary layer. A comparison is made to previous work<sup>8</sup> in a simulated cascade.

# GLOBAL INSTABILITIES IN LAMINAR SEPARATED BOUNDARY LAYER FLOW

Vassilios Theofilis

DLR Institute of Fluid Mechanics  
Göttingen, Germany

Over decades separated transitional flow control has focussed on amplification of *incoming* Tollmien-Schlichting (TS)-like disturbances and ignored the possibility of *own* ('eigen')-disturbances being generated by the flow itself. Evidence is accumulating that global flow instability is active in canonical laminar separated flow configurations. Failure to control this instability mechanism will render separated flow control methodologies which are based on TS-frequency information incomplete as far as travelling disturbances are concerned and inadequate for control of stationary global instabilities. In order to explore the question of existence of global linear instability in a model flow relevant to aerodynamics and turbomachinery alike, namely a laminar separation bubble set up by an analytically known adverse pressure gradient in incompressible flow, the related partial derivative nonsymmetric generalised eigenvalue problem has been solved<sup>1</sup>. Both stationary and pairs of travelling linear instabilities have been discovered, which are distinct from known solutions of the Orr-Sommerfeld equation (OSE) or the linear parabolised stability equations (PSE) instability theories, and can both become unstable at flow parameters presented by Theofilis<sup>1</sup>. The disturbance vorticity  $\zeta$  of the most unstable stationary global mode is dominated by the streamwise disturbance velocity component;  $|\zeta|$  is visualised in the following figure by a single isosurface of this quantity, drawn at an arbitrarily defined level such that the dominant features of the instability in question are illustrated. The flow direction is indicated by the arrow and the steady laminar separation and reattachment boundaries determined by the basic state are marked by dashed lines. One spanwise periodicity is shown. The innocuous primary separation line and the three-dimensionalisation of the primary reattachment line on account of the global instability mechanism is to be seen in this result. Of the two layers of particles released into the flow that nearer the wall, at the height of the primary separation bubble, is seen to be trapped in the neighbourhood of reattachment on account of the global instability mechanism.

Besides issues revolving around flow control, the instability mechanism discovered may well be related with and shed light to the phenomenon of vortex-shedding by laminar separation bubbles; a detailed discussion of this issue is presented by Theofilis *et al.*<sup>2</sup> In our opinion, the significance of the present findings warrants further investigation into this problem. In order to address the issues of global instability of flows with large-scale separation on configurations relevant to both external aerodynamics and turbomachinery a new algorithm based on spectral/*hp* element technology<sup>3</sup> has been developed and validated. Results will be presented in due course.

# ACTIVE CONTROL OF A TRANSITIONAL SEPARATION BUBBLE AT LOW REYNOLDS NUMBER AND ELEVATED FREE-STREAM TURBULENCE

**B. Nishri, A. Seifert, and I. Wygnanski**

Tel-Aviv University

Faculty of Engineering

Department of Fluid Mechanics and Heat Transfer

Tel-Aviv, Israel

Laminar Separation of low Reynolds number adverse pressure gradient boundary layers, with subsequent turbulent reattachment frequently occurs on airfoils and on low-pressure turbine blades. It is responsible for a reduction in efficiency due to an increase in pressure drag. Elevated free-stream turbulence (FST), enhances mixing above the separation bubble and thus promotes earlier reattachment. However, in most low Reynolds number applications, elevated FST does not eliminate the bubble altogether. Therefore, one may improve the performance by actively reducing the size of the separation bubble.

Experimental studies shown that laminar, transitional and turbulent separation bubbles can be effectively controlled by periodic excitation at low levels of FST. The control method relies on the successive introduction of coherent structures at frequencies that generate between one to four vortices at any instant above the bubble. These vortices amplify while propagating downstream, they enhance the mixing and thus promote reattachment. The fact that this method is successful for fully turbulent shear-layers served as a basis for attempting its application in the presence of elevated FST. A feasibility study was performed and reported (Bachar, Ashpis and Wygnanski, APS/DFD meeting '98) showing that active separation control is not hindered by the presence of elevated free-stream turbulence.

Current tests use an apparatus that contains a large, transitional separation bubble, situated near the leading edge of a flat-plate (Fig. 1), because the existence of a strong adverse pressure gradient. Active control, using periodic excitation via acoustic forcing from the tunnel wall (Fig. 1), is used to reduce the mean bubble size. The FST is increased by placing a grid at various distances upstream of the test plate leading edge (LE). The level of the FST varies from 0.3% to 11% (Fig. 2) depending on the position of the grid. Fig. 3 shows the turbulence length scale (using cross correlation between two hot-wires) for various FST levels. The spectral content of the oscillations in the free-stream and in the separated shear layer, were carefully documented in the presence and in the absence of "active flow control". Fig. 4 demonstrates the effect of the FST on the spectral content of the uncontrolled velocity inside and just outside the boundary layer, close to the LE. The effect of the elevated FST on the manner in which the separated shear layer is modified by the periodic excitation is documented as well. Further measurements include surface pressure distributions (Fig. 5 shows the effect of the FST on the mean  $C_p$ 's) as well as mean and fluctuating velocity profiles that are phase locked to the excitation..

Preliminary results indicate that the average dimension of the bubble can be significantly reduced, even in the presence of elevated FST. This particularly true at the low frequency of excitation (e.g. 20Hz, corresponding to  $F_B^+ = 1$ , where the reduced frequency is based on the length of the baseline bubble and the free-stream velocity) when there is a large disparity of scales between the free stream turbulence and the imposed oscillation. At an excitation frequency of 80Hz, the effect of AFC was reduced as the FST increased. See Fig. 6 for controlled  $C_p$ 's. The effect of acoustic excitation from the tunnel wall was found to be similar to the effect of a vibrating ribbon placed near the LE of the plate (Fig. 7)

It is believed that the application of active flow control to low Reynolds number axial flow machinery has great potential for improving efficiency of a single rotor-stator stage therefore enabling a reduction of overall number of stages simplifying future design. (see Fig. 8 for provisional conclusions)

# STABILITY, TRANSITION, AND REATTACHMENT CHARACTERISTICS OF A SEPARATION BUBBLE IN UNSTEADY FLOW

**J. Hourmouziadis**

Jet Propulsion Laboratory, Aerospace Institute F1  
Berlin University of Technology  
Berlin, Germany

Highly loaded turbomachinery airfoils in high lift low pressure turbines as well as in compressors approaching stall demonstrate transition of the suction side boundary layer via a separation bubble. Close control of this transition process is necessary to avoid full separation with dramatic effects on performance and stability.

The transition of the free shear layer is strongly affected by two unsteady external phenomena:

- the velocity defect in the wake of upstream blade rows and
- the increased turbulence levels within this wake

In most experiments both phenomena are effective simultaneously and it is not possible to determine their relative relevance. Experiments with a large-scale low-speed facility offer the opportunity of combining a closely controlled main flow with a detailed resolution of the shear layer. Such experiments have been performed in a suction type wind tunnel with a rotating flap and a contoured wall to generate the necessary pressure distribution on a flat plate. The effects of the velocity defect of the wake alone are studied in a low-turbulence environment. Typical parameters have been selected from earlier high speed turbine tests.

The results offered for discussion include

- A comparison of the response of the separation bubble to steady and periodic main flow.
- The development of instability waves in the free shear layer and visualization of the transition process over a full period of the main flow fluctuation applying phase-averaging to single hot wire signals.
- The characteristic "frequency packages" of the instability waves
- The observed phase shift between the main flow and the separation bubble in the region of transition and reattachment.
- The effect of Strouhal-no. on the location of transition initiation along the velocity wave of the periodic main flow.

## **SIMULATIONS OF BOUNDARY LAYER DEVELOPMENT IN LOW-PRESSURE TURBINES**

**Daniel J. Dorney\***

Virginia Commonwealth University  
Department of Mechanical Engineering  
Richmond, VA

Experimental data from jet-engine tests have indicated that turbine efficiencies at takeoff can be as much as two points higher than those at cruise conditions. Recent studies have shown that low Reynolds number effects contribute to the lower efficiencies at cruise conditions. The goal of the current effort is to implement/improve existing turbulence models, natural transition models, intermittency function models and bubble transition models into two- and three- dimensional Navier-Stokes analyses. Numerical simulations have been performed for several geometries, including a low-pressure turbine cascade and a two-stage low-pressure turbine. The simulations were performed for several Reynolds numbers and turbulence levels. The predicted results have been compared with experimental airfoil loadings and boundary layer quantities. The comparisons indicate that relatively simple models can be used to predict the effects of Reynolds number variations in a low-pressure turbine environment.

## **EFFECT OF FAVORABLE PRESSURE GRADIENTS ON TURBINE BLADE PRESSURE SURFACE HEAT TRANSFER**

**R.J. Boyle**

National Aeronautics and Space Administration  
Glenn Research Center  
Cleveland, OH

**P.W. Giel**

Dynacs Engineering Company, Inc.  
Cleveland, OH

Recent measurements on a turbine rotor showed significant relaminarization effects. These effects were evident on the pressure surface heat transfer measurements. The character of the heat transfer varied with Reynolds number. Data were obtained for exit Reynolds numbers between 500,000 and 880,000. Tests were done with a high level of inlet turbulence, 7.5%. At lower Reynolds numbers the heat transfer was similar to that for laminar flow, but at a level higher than for laminar flow. At higher Reynolds numbers the heat transfer was similar to turbulent flow, when the acceleration parameter,  $K$ , was sufficiently small.

The proposed paper discusses the experimental results, and also discusses approaches to calculating the surface heat transfer for the blade surface. Calculations were done using a three-dimensional Navier-Stokes CFD analysis.

The results of these tests, when compared with previous blade tests in the same facility, illustrate modeling difficulties that were encountered in CFD predictions. The two blades were in many ways similar. However, the degree of agreement between the same analysis and the experimental data was significantly different. These differences are highlighted to illustrate where improvements in modeling approaches are needed for transitional flows.

# **MIXED-FLOW TURBINE: STEADY AND UNSTEADY PERFORMANCE WITH DETAILED FLOW MEASUREMENTS**

**Ricardo F. Martinez-Botas**

Imperial College  
Department of Mechanical Engineering  
London, U.K.

Turbochargers are finding increasing application to automotive diesel engines as cost-effective means for improving their power output and efficiency, and reducing exhaust emissions; these requirements have led to the need for highly loaded turbocharger turbines. A mixed-flow turbine is capable of achieving its peak isentropic efficiency at reduced velocity ratios compared to a typical radial inflow turbine, it is therefore possible to improve the turbocharger/engine matching.

The steady and unsteady performance of a mixed flow turbocharger turbine with constant blade inlet angle has been investigated. The steady flow results indicated that the mixed-flow turbine obtains a peak efficiency (total-to-static) of 75% at a velocity ratio of 0.61, which is lower when compared to a typical radial inflow turbine (peaking at around a 0.7 velocity ratio). In the unsteady flow performance tests, the cycle average isentropic efficiencies are higher for the mixed flow geometry than in a radial turbine. A substantial deviation from the performance and flow characteristics of the equivalent steady-state tests commonly used in turbocharger turbine design has been found. The pulsations from the engine have been followed through the inlet pipe and around the volute; the pulse has been shown to propagate close to the speed of sound and not according to the bulk flow velocity as stated by some researchers.

The flow entering and exiting the blades has been quantified by a laser Doppler velocimetry system. The turbine test conditions corresponded to the peak efficiency point at 29,400 and 41,300 rpm. The results were resolved in a blade-to-blade sense to examine in greater detail the nature of the flow at turbocharger representative conditions.

The unsteady flow characteristics have been investigated at two flow pulse frequencies, corresponding to internal combustion engine speeds of 1600 and 2400 rpm. Four measurement planes have been investigated: one in the pipe feeding the volute, two in the volute ( $40^\circ$  and  $130^\circ$  downstream of the tongue) and one at the exit of the turbine. The pulse propagation at these planes has been investigated; the effect of the different planes on the evaluation of the unsteady isentropic efficiency is shown to be significant. The rotor inlet and exit velocity triangle under pulsating flow conditions has demonstrated a deviation from the optimum conditions based on steady-flow analysis.

# THE EFFECT OF TURBULENCE LENGTH SCALE ON LOW PRESSURE TURBINE BLADE HEAT TRANSFER

**Robert J. Butler**

Unpredicted losses during high altitude operation have been observed in low pressure gas turbine stages. These losses have been attributed to separation on the suction surface of the turbine blades. To gain insight into boundary layer transition and separation for these low Reynolds number conditions, the heat transfer distribution on a Langston turbine blade shape was measured in a linear cascade wind tunnel for turbulence levels of 0.8% and 10% and Reynolds numbers of 40k to 80k. Turbulence levels of 10% were generated using three passive biplanar lattice grids with square-bar widths of 1.27 cm, 2.54 cm, and 6.03 cm to investigate the effect of turbulence length scale. The heat transfer was measured using a uniform heat flux liquid crystal technique. As turbulence levels increased, stagnation heat transfer increased and the location of the suction-side boundary layer transition moved upstream toward the blade leading edge. For this turbine blade shape the transition location did not depend on turbulence length scale, the location is more dependent on pressure distribution, Reynolds number and turbulence intensity. For the 10% turbulence cases, the smaller length scales had a larger affect on heat transfer at the stagnation point. A laser tuft method was used to differentiate between boundary layer transition and separation on the suction surface of the blade. Separation was observed for all of the low turbulence (clean tunnel) cases while transition was observed for all of the 10% turbulence cases. Separation and transition locations corresponded to local minimums in heat transfer. Reattachment points did not correspond to local maximums in heat transfer, but instead, the heat transfer coefficient continued to rise downstream of the reattachment point. For the clean tunnel cases, streamwise streaks of varying heat transfer were recorded on the concave pressure side of the turbine blade. These streaks are characteristic of Görtler vortices. For the 10% turbulence cases, these streaks were not present. The results presented in this paper show that turbulence length scale, in addition to intensity have an important contribution to turbine blade aerodynamics and are important to CFD modelers who seek to predict boundary layer behavior in support of turbine blade design optimization efforts.

## **ESTIMATING TRANSITION LOCATION IN THE PRESENCE OF ROUGHNESS AND FREE-STREAM DISTURBANCES**

**J.D. Crouch and L.L. Ng**

Boeing Commercial Airplanes  
Aeroacoustics and Fluid Mechanics  
Seattle, WA

Receptivity analysis is used in conjunction with linear stability theory to estimate the location of transition for various model-surface finishes and free-stream-disturbance environments. Tollmien-Schlichting instabilities and cross-flow instabilities are considered in the context of swept-wing transition, in low to moderate free-stream-disturbance environments. Receptivity studies include acoustic and vortical free-stream perturbations, surface roughness, and nonuniformities in surface suction.

With simplifying assumptions about the receptivity, a variable n-factor method has been formulated for transition due to cross-flow instabilities. Transition is correlated with the stationary cross-flow vortices for turbulence levels characteristic of flight. At higher turbulence levels, the transition is correlated with traveling cross-flow instabilities. In both cases, the n-factors vary with the surface-roughness level, consistent with a simplified model of non-localized receptivity at the instability neutral points.

In many technical applications, laminar boundary layers are induced, by roughnesses, to undergo transition to a turbulent flow at lower Reynolds numbers than the natural flow transition. The present studies were undertaken to extend the knowledge of the spatial and temporal structure of the transition process induced by a single square roughness element. Particular emphasis was placed on the evolution of the viscous layer since it usually dominates the convective resistance to heat transfer (and momentum transfer) to/from a surface. The aim is to reach a better understanding of the fluid physics structure which evolves in a transition process induced by roughnesses, especially in the near-wall region. The results should also be valuable for benchmarking Direct Numerical Simulations of transition enhanced by the presence of roughness elements.

To measure the wall-normal component close to the surface, two-component laser Doppler anemometry (LDA) was used with the INEEL Matched-Index-of-Refractive (MIR) flow system. With hot-wire and hot-film X- or slant-probes to deduce Reynolds shear stresses, the sensor volume required has a dimension of the order of a millimeter perpendicular to the surface plus the additional space necessary for the support prongs. With LDA, an effective sensor diameter of about 60  $\mu\text{m}$  or less can be achieved so measurements can be obtained to  $y = 30 \mu\text{m}$  before "intersecting" the surface. However, the wall can interfere with the laser beams of an LDA system, especially when systems for two- and three-component measurements are employed. One way to eliminate these problems is to use a liquid possessing a refractive index that is matched to that of the wall material. The INEEL MIR flow system provides a basic test facility to study boundary layer transition in detail. The length of the test section is about 2.4 m and it has a cross section of about 0.61 m x 0.61 m, compared to other MIR facilities which have characteristic dimensions of a few centimeters.

Measurements of flat plate boundary layers were carried out with three different roughness heights  $k$  and three different freestream velocities, resulting in the following ranges of parameters:

$$k^+ = 5.9 \text{ to } 22; 6 \times 10^4 < \text{Re}_{x,k} < 1.5 \times 10^5; \text{Re}_\Theta < 560; 2.5 < (x-x_k)/k < 580$$

The LDA system yielded data to a distance as near to the wall as  $y^+ = 0.1$  and less. Thus, it was possible to estimate the local apparent wall shear stress accurately from the measured gradient  $\partial U / \partial y$ . Most of the data were acquired with a two-component LDA operating in the forward scattering mode, thereby permitting simultaneous streamwise and normal velocity component measurements and calculation of their higher-order moments to be performed. The distributions of the nondimensional profiles  $u^+$  and  $y^+$  will be presented as well as development of the fluctuating turbulent components  $(u')^+$  and  $(v')^+$  and of the Reynolds shear stress in the viscous layer.

In addition to presentation of the results of this recent experiment, plans will be discussed for a comparable upcoming study using the INEEL MIR system. For the DoD-EPSCoR/AFOSR program, Prof. Ralph S. Budwig of the University of Idaho will measure the fluid physics of turbulent and transitional flow over roughnesses characteristic of realistic surfaces of turbomachinery blades. Idealized surface models will be developed from the WPAFB database in collaboration with AF technical representatives.

# A BASIC NOZZLE TEST FACILITY FOR FLUID-STRUCTURE INTERACTION IN TRANSONIC FLOW

**T.H. Fransson and O. Bron**  
Royal Institute of Technology  
Chair of Heat and Power Technology  
Stockholm, Sweden

## ABSTRACT

A prerequisite for aeroelastic stability investigations in turbomachines is the understanding of the aerodynamic forces acting on the blades. In order to obtain precise insight into aeroelastic phenomena associated with oscillating shock waves, fundamental experiment to further understand the behaviour of travelling pressure waves in non-uniform transonic flows at different operating conditions are needed. The emphasis is on the unsteady interaction of upstream propagating acoustic waves with a shock in transonic convergent-divergent nozzles at different inlet boundary layer conditions, and how this interaction can affect the unsteady pressure distribution on the surface. This presentation intends to present the facility in which those experiments are being performed, and give an overview of the intended future modifications and investigations. Different test objects and their instrumentation will be presented as well as the first preliminary results.

$\nu$	Fluid viscosity

## INTRODUCTION

Transonic flows about streamlined bodies are strongly affected, particularly near the shock location, by unsteady excitations. Experimental and computational studies [1,3] have shown that the unsteady pressure distribution along the surface of an airfoil or a cascade blade in unsteady transonic flow exhibits a significant bulge near the shock location. Tijdeman and Seebass [11] reported that the unsteady pressure bulge and its phase variation resulted from non-linear interaction between the mean and unsteady flow. This non-linear interaction causes a shift in the shock location, which produces the observed large bulge in the unsteady pressure.

Studies [5] on choked flutter have shown that, in unsteady transonic flows around a single airfoil, the

shock motion, and then the pressure distribution along the surface, can be critical regarding to the self-exciting oscillation of the airfoil. It was also found that the mean flow gradients are of high importance regarding the time response of the unsteady pressure distribution on the airfoil surface. Moreover, numerical computations [4] have shown that the exact location of the transition point could strongly affect the prediction of stall flutter.

Further studies [2] suggested that this sharp rise in the unsteady pressure distribution was due to the near sonic condition, and that the near-sonic velocity acts as a barrier they called *acoustic blockage* preventing acoustic disturbances from propagating upstream in a similar way to the shock in transonic flows. A transonic convergent-divergent nozzle experimentally investigated by Ott et al. [10] was thereafter used as a model to investigate the non-linear acoustic blockage. Analytical and numerical computations [6,7,8,9] were then carried out to analyse and quantify the upstream and downstream propagation of acoustic disturbances in the nozzle.

## OBJECTIVES

The objective is here to present the facility which is used to study the unsteady interaction of upstream propagating acoustic waves with a shock in transonic flow, and its intended modifications to add incoming wakes and a fluctuating wall.

## TEST FACILITY

Experiments are performed in the nozzle test facility, which was designed to be highly modular so that different test objects, so called "bumps", can be inserted in a 100x120mm square test section. A 1MW compressor provides a maximum mass flow up to 4.7 kg/s at 4 bars and 30°C. A cooling system also allows a temperature range from 30°C to 180°C, and the adjustment of different valves controls the mass flow and the pressure level in the test section. A special design allows the test objects to be raised up in order to cut off the boundary layer to the atmosphere (see fig.1). As a result, different inlet Mach number (from  $M=0$  to 0.8) as well as different Reynolds number (from  $Re=U.d/\nu=54,000$  to 22,000,000) can be reached.

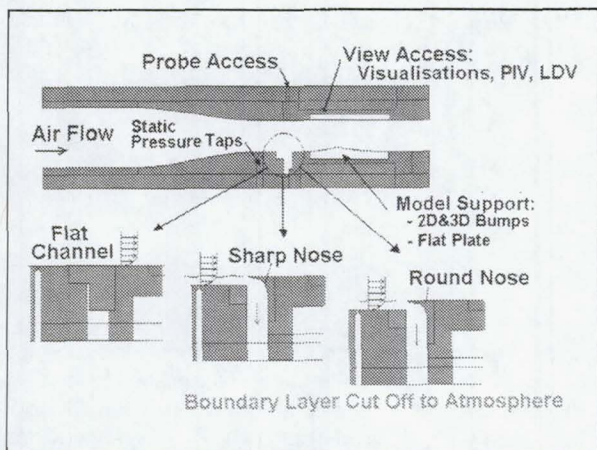

Figure 1: Schema of the nozzle test facility

## FIRST TEST OBJECTS AND INSTRUMENTATION

A first test object consists of a long two-dimensional (2D) bump which can slide through the width of the test section. This bump is equipped with one row of 80 hot film sensors, and three staggered rows of 50 pressure taps each. Thus, a complete mapping of the steady and unsteady pressure distribution over the channel width is possible, as well as the determination of the boundary layer state on the bump.

A second test object consists of a three-dimensional (3D) bump which was numerically designed to create different local accelerations of the flow through the width of the test section. The design parameters were the length and the thickness of the bump, as well as the throat line position. As a result, the shock wave is slightly bent instead of being perpendicular to the main flow direction. This special shape of the nozzle will allow to study the influence of the mean flow gradients on the shock motion. Among four models available for instrumentation, one is instrumented with 350 pressure taps (fig.2).

Figure 2: Instrumented 3D bump

Regarding unsteady measurements, a rotating ellipse placed downstream of the test section is used as a pressure wave generator with frequency up to 600 Hz.

As a result, pressure perturbations propagate upstream at a speed which is function of the local flow velocity, and interact with the shock wave. Unsteady pressure measurements are performed using standard Kulite transducers instrumented on the same test objects as for steady state measurements.

## MEASURING TECHNIQUES

Pressure measurements will be performed using a 200-channel 'steady state' pressure data acquisition system from PSI (up to 300Hz on each channel, and  $\pm 0.05\%$  full scale accuracy), and a 32-channels transient system (up to 20kHz sampling). The boundary layer behaviour is investigated with surface mounted hot films, hot wire traverses, LDA measurements and surface oil visualisations. A conventional Schlieren system is used to monitor the shock motion in the 2D nozzle using a high speed camera (up to 8000 pic/s). A state-of-the-art three dimensional Laser-Two-Focus Anemometer (3D-L2F) will be employed to measure the 3D mean velocity vector and the turbulence intensity at the inlet boundary as well as at different stations in the test section. PIV measurements are also foreseen in the future.

## ACKNOWLEDGEMENT

The authors wish to thank STEM (project 6303) for their financial support.

Leicester, U.K.

### Breakout Sessions Reports and Discussions

Okiishi: We've got four hard working groups that have been spending some time together talking about various ideas and we are going to hear their reports now. About ten minutes each. To gain some perspective, this workshop is about transition in flow and turbomachines and is a vehicle for using this knowledge. So as each of the groups comes up to report we need to keep in mind these two things. We are talking about boundary layer transition, impacts of the transition and what impacts transition. And particularly on transition that occurs in turbomachines. So let's try to keep our eyes on those two drivers. We have a by-pass group. That is going to be reported on by Greg Walker and then we have a group that concerned itself with flow separation details and George Huang is going to report for that group. Then we have a group that looked at the whole gas turbine engine and tried to address the question of what are the disturbances that would impact transition in some way. Finally we have a calming group. So, Greg, start talking.

### By Pass Transition

Walker: We had fourteen people participating in the by-pass transition group and we led off on that subject. It was agreed that the definition and concepts of by-pass transition had changed over time since the term by-pass was first coined by Morkovin. Morkovin's original idea was "that phenomenon which by-passes known transition modes". There was no universal agreement on what the current definition should be but some suggestions or comments on what attributes it might have are, firstly: the original definition of Morkovin as "that which by-passes all known theories". Secondly, and this was a major attribute, "that process which is non-linear from the beginning and shows no evidence of linear amplification". As a corollary of that we might say "any process which gives earlier transition than would be predicted by the e<sup>n</sup> method". It was agreed that free-stream turbulence was not a good basis on which to define by-pass transition as laminar flow was observed up to 30% of free stream turbulence under some circumstances and certainly our observations indicate it does not necessarily follow that a high level of free stream turbulence implies that we will have by-pass transition. Another factor to take into account in by-pass transition is that the shape of the turbulent spots may be quite different from those of the classical arrowhead shaped spots that are observed under zero pressure gradient natural transition conditions and this may be due to the surrounding flow being unstable if the by-pass mechanisms cause the breakdown to occur earlier. There was some disagreement on whether we should classify transition under a mean flow distortion as by-pass. Some thought we should, others thought that this was merely an example of changing the receptivity of the flow. I think the general conclusion is that because of this diversity of opinion that we should be careful to define the term by-pass whenever we are using it and one of our members, to be rather provocative, asked the question "Do we need to use the term by-pass anyway"?

Preceding . . . . . blank

Getting on to natural transition, this is complementary to by-pass transition and it was suggested here that it might be better to use the term "canonical transition"; that is something that follows a known route for this process. Natural transition can include situations where the disturbance environment is altered by design and perhaps it would be better to use the term controlled transition for this sort of case because there will always be forcing of the disturbances in the boundary layer by the natural environment in any case. It was agreed that transition resulting from point disturbances which led to three-dimensional wave packets showing an initial stage of linear amplification should probably be classified as natural transition and as a result of that it would appear that we are correct in classifying the observations from Hughes' experiments of wave activity in decelerating flow transition, on our compressor blades, as characterising natural transition. The final topic we touched on briefly was sub-transitions and it was agreed that these were characterised by relatively abrupt changes in the intermittency distribution within the transition zone, which caused it to differ from the standard intermittency distribution of Dhawan and Narasimha. It was agreed that the situation of transition followed by re-laminarisation followed by re-transition did not really fall into a class of sub-transitions. Someone suggested that it would be useful to see whether there were new spots being formed at a sub-transition, although it seems rather unlikely because sub-transitions normally occur fairly well into the transition zone, where the ability to form new spots is restricted by the increasing proportion of turbulent flow. It was agreed that the most probable explanation for sub-transitions in spatially varying flow where we have a rapidly varying pressure gradient along the surface is most probably due to changes in the rate of growth of turbulent spots. These are particularly pronounced where we change from an accelerating flow to a decelerating flow within the transition zone and that is the situation that is prevalently found on the suction surface of low-pressure turbine blades. That concludes my report.

Okiishi: Good report Greg. You've earned your group some discussion time. Would the group stand so that we can identify you. Any comments or questions?

Clark: Having been in that group I don't remember us agreeing that it was most likely not the increasing rate of spot generation. I remember arguments being made but I don't remember us reaching a consensus. So I disagree with the conclusion that was drawn.

Okiishi: So you would call that an unresolved question.

Walker: I mentioned two possibilities there. One possibility was the number of new spots generated through the transition zone varying. The other was the changing rate of growth of spots through the transition zone. I thought there was a majority opinion that the latter effect was likely to predominate.

Corke: I think the situation that we had in mind that might create new spots was when a shock impinged on a transition zone. Because of the severe adverse pressure gradient in that case it was not clear that new spots would not be formed.

Walker: I would certainly agree with that.

Okiishi: This is good. We are getting some pertinent information from this group.

Simon: Under that definition is by-pass transition reserved for only attached flow transition? It is not applicable to transition of a shear layer over a separation bubble?

Walker: I don't know that I would have separated flow transition as a separate class. I would say that you either have natural or by-pass transition and that can cover either attached or separated flow. That's my personal view.

Povinelli: I wonder about Roddam's term sub-transitions, because I get the impression that what you are describing might be called the actual transition that occurs when there may have been some other type of transition beginning and this other one came along and dominated and caused the final transition. So sub-transition sounds like an inappropriate way of describing it. I have the feeling there must be a better term.

Narasimha: I certainly can propose one. The only reason I called it sub-transition was that it occurs within the transition zone. There is this main transition from laminar to turbulent flow going on. Within that zone there is some kind of change that takes place.

Clark: It seems that we identify the sub-transition from a change in slope of an  $F(\gamma)$ . What can cause that change in slope is either  $N$ ,  $\sigma$  or  $U_{inf}$ . So if we define the sub-transition to find an identification of it by that change in slope I don't think we can judge *a priori* that it was simply sigma that changed.

Narasimha: I think that is correct. That is why I would like to make a distinction. This is a personal view. I would like to make a distinction between sub-transitions and the reasons for sub-transitions. As I said a minute ago, the sub-transition is noticeable as a relatively abrupt change. But of course within the transition zone the only reason for adding the word sub is that there are other transition processes going on already. I think they are right. In principle you can't tell. I don't think there is enough experimental data yet to tell whether it is caused by the number of spots being made or by the propagation characteristics. This is something you have to settle by more work.

Okiishi: What is your group's intention with regard to recording this.

Walker: We could write this up and include it in the proceedings of the meeting.

Gostelow: What will happen is that the words being recorded there will find themselves transcribed in writing as in the previous conference and find themselves in the proceedings, pretty well verbatim, unless you decide otherwise.

## **Flow Separation**

Okiishi: Let's move on to the next group, which is the flow separation group. George Huang will report for that group. Let's have that group stand up so that we can see who was in it.

Huang: The group you see met twice. John joined us in the second meeting. In the first meeting we all agreed on everything. After John arrived we disagreed again. After about ten minutes we all agreed again. We started the meeting talking about prediction, 2D prediction. Some questions were raised whether 2D prediction is valid.

We believe that separation is easily categorised into 2D, but that reattachment is a 3D phenomenon. So we think that we should look at 3D instabilities before we go onto a prediction method. We think that perhaps we should gain better understanding about the stability of the bubble. That would help us in predictions. We talked about instabilities not only in terms of a bubble's shear layer instability, we also have to look into the global instability. We believe that there is some kind of global instability inside the bubble that would give rise to a feedback mechanism with a Strouhal number of about one. And we believe it is important that we should look into that as well. We also touched upon the point that the Roberts correlation that many people use is actually from 1975; it's really out of date. Maybe we should come up with a better correlation. We should look into that direction as well. We also say that "When we classify the bubble is there only one type of bubble or should we classify different types of bubble, such as long bubble, short bubble" and we want to look at the instability of the different types of bubble. Look at their similarities, look at the differences. Perhaps that will help us in understanding the separation phenomena. And we think that in terms of prediction the leading edge short bubble is probably easier to predict. The long bubble is probably most susceptible to global instability; perhaps this is more difficult to understand and also to predict.

We also talked about "Maybe we should design an experiment, because reattachment is more of a 3D phenomenon it is harder to predict and the separation is easier, perhaps we should devise an experiment which would have a fixed bubble and then we can prescribe some free stream turbulence and look at how the reattachment is influenced by the free stream". Can we devise an experiment, one that was talked about was the backward-facing step. But another member of the group said "We have seen so many backward facing step experiments - we don't need another one". But perhaps we can look into some kind of turbomachinery-related problem because probably we can identify a problem that will give us more insight into these phenomena.

One member in the group is more from a modelling background. He wanted to see an experiment that had transition taking place just before separation. Also another set of experiments should see the transition take place more on top of the bubble; we need more experiments of those type. One is to look at by-pass transition, the other to look more at shear flow transition.

We talked about the length scale and had a lot of debate about that. We wanted to know what is the length scale in bubbles. We agree that both the length scale and the turbulence level are important but we wanted to know what length scale we should define. Perhaps we should classify the length scale: identify all the possible length scales that are important, such as the turbulent length scale, the bubble length scale and perhaps document them. When we talk about documentation we asked what results do we need from experiments. We came up with a conclusion you may not agree with. We think of all experimental data the raw data is the one that everyone has to store. Because one day you might want to go back to the data and look in a different way at the data. We spent a lot of time discussing the best way to store the data. ASCII or some other form? Perhaps we should put it into a format that is accessible to all members in the group.

One more thing before we end. One member raised the issue “Now you talk a lot about stability, bubbles etc. How does that help us in modeling? Are we missing something? Do we have a problem bridging the two. The modeler and the person doing the stability analysis. How do we bridge the two?” That is the question at which time was up.

I said we need all experimental data. We need time domain, frequency domain, everything to be documented - everywhere.

Fransson: Coming from outside this community I think it would be very useful to us to know what I should look at in detail for your kind of problems. It would be very useful to have a list of priorities with what would you like to see measured, how would you like to see it measured, if possible, and with what priority.

Huang: I think that is a good point. The way we approached this discussion is that we adopted a top down approach, not a bottom up approach. The experimentalists tell me “I am measuring this, I am measuring that, I have this much information. I have to think about how to digest the information on instabilities etc. for the model”. Perhaps next time we should do it in a different way - we should ask the modelers to pose the question to the experimentalists: What do they need?

Okiishi: They need to understand the phenomenon first.

Huang: As well. Both ways.

Fransson: From my perspective it would be very useful if a conclusion from this today would be a list of information that you would like to have in order to model your problem. I know what I need in order to model my problem but I do not know what you would need in order for us to connect. If you could give me a list of priorities that would be perfect and we will try to give you that information. And probably I will also learn something from that at the next meeting.

Okiishi: Other questions or suggestions?

Smith: There have been countless experiments in the past on separating flows and also computations.

Gostelow: Have there been any good experiments on separation?

Smith: I am the last person to ask about that. There were some experiments done in Scandinavia by a PhD student in the late 90's that were reported in a meeting two years ago. He was talking about transition ahead of separation and beyond.

Theofilis: I want to answer in an abstract way. Maybe what is on the board is the answer. It is not about repeating the experiment. It's about doing the experiment for different things and conditions.

Herbert: We may take down a copy of Mark Morkovin's list of preferences.

Okiishi: How succinct is the list? A couple of pages?

Hodson: It could be appended to a CD.

Walker: I think what Torsten is suggesting for the aeromechanical problem is something new. These are observations from a separating flow on an oscillating surface. Not only is the flow oscillating but also the boundary surface is moving so I think it important that the motion of the bounding surface should be accurately prescribed as well if we are going to interpret the data properly.

Fransson: That I know how to do, so I could easily give that information. That is fairly easy from my perspective.

Industry: I think there are some tests that need to be redone. Particularly if you try to apply the models that are developed in comparison against experimental data where not enough information is taken, such as special information about turbulence intensities, things of that nature. Some of these need to be redone.

Okiishi: Do you have any experiments planned for your rig, Don? Separation bubbles, detailed measurements?

McEligot: Not specifically. We don't have any funding for doing anything like that. We do have the flow over a building model and there will certainly be recirculation zones behind that, the flow will be separated but it is not a turbine blade.

### **Turbulent Spots and Calmed Region**

Okiishi: Let's move on to spots and the calmed regions that go along with the spots. What do you call them Paul?

Gostelow: Blobs. I'm trying to think of a less drastic name.

Johnson: No - blobs it is. We started out with three people and expanded to eight. The objective was to define what we really mean about the spot or the calmed region and to talk a bit about the characteristics of these regions. We also decided after my presentation that spots should be red and calmed regions should be blue.

The definition we came up with was that a spot was a distinct region inside which the flow has turbulent boundary layer characteristics. We tried to qualify the characteristics but decided that included everything, such as profiles, Reynolds stresses, everything that you can measure within that. We had some problems with the region. We started out with bounded region, confined region, so we were uncertain about that.

A spot usually propagates. We debated whether the word usually should be within that and decided that it should.

Regarding the characteristics, we thought that once fluid has entered the spot it cannot leave the spot. There are, of course, spots that do not meet the classical Emmons spot model. We have seen that very much at this meeting. We tried to cover that in the following two statements:

An embryo or early spot will exhibit some form of structure.

Also we have the sub critical spots which are induced by some other disturbance, free stream turbulence or wake-passing. These have these rather odd shapes and also grow at these rather lower rates so they basically have rather different dynamics. It is suggested that maybe these sub critical spots are most relevant in turbomachinery.

So after the spots we switch to the calmed region. Definition: Again we felt that the calmed region always has to be associated with some form of turbulent region, such as a turbulent spot, strip or blob, as defined by Paul Gostelow. Or a wave packet, so you can have a calmed region behind a wave packet as well. And it will always have a fuller profile than a laminar boundary layer. The profile within the calmed region relaxes from that fuller (more stable) profile back towards the laminar profile. That is supported both by the types of models that use unsteadiness and viscous diffusion and also by numerical flow visualisation which supports that.

As far as the fluid is concerned all the fluid enters the spot by its trailing edge. So there is no fluid that passes from the spot into the calmed region. We seemed fairly convinced that that was the case. So the calmed region, it has often been said, results through a rapid relaminarization. We are saying that that is definitely not the case. That the calmed region is not formed by relaminarization of the spot fluid.

Okiishi: Let's have some questions, comments and suggestions.

Hodson: The blue stuff looks identical to what it did three years ago. Is that correct?

Ramesh: Well, the calmed region hasn't changed.

Hodson: I'm glad I didn't join the group then. On your red stuff, I think you said fluid never leaves spots. We did an experiment five or six years ago where we had a flow transitioning before it flowed over a porous surface, which had suction below it. The intermittency dropped as you went over the surface. I never worked out whether the spots were getting smaller or we were relaminarizing. If the spots were getting smaller, which is what I suspect was happening, then, in a sense, fluid is leaving the spots

Hourmouziadis: If you suck the flow from the spots what do you expect?

Okiishi: You'd accept that exception, right?

Hodson: I wonder if there is anything in that.

Gostelow: You are not supposed to do that though.

Durbin: The spot is a wave packet and in general the wave doesn't move at the same speed as the fluid.

Herbert: You can get diffusion out of the packet.

Seifert: I think we are smiling because there is a famous experiment by Gad el Hak and others. They generated a spot with a puff of coloured fluid. They generated the spot and they never saw the colour leaving the spot. A spot is wavy, of course, it is a shear flow disturbance. But the convection speed is such that in general particles entering it will not leave it. Perhaps a coincidence or perhaps not but I think it is a fact.

Hourmouziadis: Simply the kinematics would suggest that. The thing cannot convect as fast as the rest of the fluid does. So there are two alternatives. It is either a solid blob moving through the fluid or there is some fluid coming in and getting out. The phenomenon is moving slower than the rest of the flow.

Jones: This is why our definition is so valuable.

Walker: The surrounding fluid actually rides under and over the spot. So the spot actually appears to the rest of the flow like a perturbation in displacement thickness. You can actually pick the spot going past by looking at the perturbations in the free stream velocity. So fluid does not have to go into the spot. It can go around it. It looks like a solid body. It stays with the spot and moves with it, then more gets accumulated into it and the surrounding fluid is also moving around it and over it.

Narasimha: I believe that in a well-developed spot, of the kind that Gad el Hak and others have studied. It is true that the fluid that goes into a spot does not get out in general. However I would hesitate a great deal to make that a defining characteristic of a spot. Because, as we have discussed during this meeting, there are all kinds of different spots. The initial spot, the sub critical spot, blobs and so on. There is no doubt in my mind that there are varieties of situations in which a fluid, when it becomes turbulent, can get out and leave that turbulence. Of that I've no doubt. Why - because we know of a variety of situations in which we know that, at least locally, fluid is getting out as well as getting in. Getting in at one place and getting out at another place. So I feel that it should not be made a defining characteristic of a spot because if you did so then of course you are constraining a spot to be an extremely specific entity. You can always take the view that if in fact fluid gets out of a spot you could make it a part of the definition. So I feel that it is good to use the word spot (or blob) as any island of turbulence. That island may grow, that island may shrink, it can do a variety of things. I think we should try and see in every situation what it does. There may be situations where the island shrinks, as Howard was saying, and fluid does get out. So I don't think we should say that we then not call it a spot.

Smith: I don't think you can make that the definition of a spot. This is a property for which the added word usual applies.

Narasimha: If you say "usual" or if you say "fully developed spot" I agree.

Jones: That is what was intended. Other spots we called sub-critical or something else and we didn't attribute that property to those other spots. Only to the fully developed Emmons-type spot.

Okiishi: So, once again in view of Mount Emmons we have had a very good discussion on spots. Now on to the final group for discussion of the engine disturbance environment.

## **Engine Disturbance Environment**

Murawski: What is the engine disturbance environment? What do we know about the combustor? Let's ride through the turbine!  
[Displayed charts:]

### Looking at the turbine exit and into the IGV (Inlet Guide Vanes)

Turbulence Intensity, Length Scale, Total Temperature, Temperature and Velocity Profile, Low Velocity, Low Ma (0.1), Possible Hot Streaks, Possible Chunks of Carbon, Turbulence Decay Rate.

### In the IGV

Leading Edge Showerhead Cooling, High Turning Curvature, Stable Secondary Flow, 1.1 – 1.2 exit Ma, Surface Film Cooling, Surface-to-Freestream Temperature Difference, Surface Roughness (TBC Spallation), Shocks, Reflected Shocks, Potential Downstream Rotor Interaction, Hot Streaks, Film Cooling Freestream Mixing.

### Out of the IGV and into the First Stage HPT Rotor

Wakes, Shocks, Huge Secondary Flows, Unsteady Purge Leakage Flows, Reflected Shocks, Trailing Edge Cooling, Hot Streaks.

### In the First Stage HPT Rotor

(In the IGV) + (Out of IGV) + (Tip Leakage, Film Cooling, Aero-Elasticity of the Blades, Centrifugal Force Effecting Film Cooling Outlet 1.3 Ma)

## ENGINE OPTIONS

Purge Flows

Lower Pressures and Lower Re

We may group these disturbances into the following categories:

#### NON-ROTATING – NATURAL DISTURBANCE

*(Always in turbomachinery)*

- Pressure Gradients, Axial Velocity, Ma Gradients:
- Curvature:
- Temperature Difference ( $T_w - T_{\text{freestream}}$ )
- Shocks:
- Reflected Shocks:
- Secondary Flows:
- Endwall Separation:
- Aspect Ratio:
- Turbulence Transition / Separation:

#### NON-ROTATING – DESIGNED DISTURBANCE

*(Choice by design)*

- Film Cooling:
- Surface Roughness:
- Hot Streaks:
- Purge Leakage Flows:
- Struts (wakes, profile loss, secondary flows):

#### ROTATING – DESIGNED DISTURBANCE

*(Choice by design)*

- Tip Clearance:
- Aero-Elasticity:
- Centrifugal Force Effects on Film Cooling:
- Wakes:

The important question is what should happen next?

Each of these quantities is considered by the designer and we need to determine what the designers need for input. Something quantitative out of these issues that were mentioned. That quantitative information is to ask the designer exactly what they put into their models. What we should do is to take each of those disturbance effects that we listed and discuss how each of these disturbances affects boundary layer transition in about two to five sentences only. Then quantify each of the impacts on transition, with references, in one to two sentences. So for each of these issues listed we should succinctly, in about 7-10 sentences per issue, wrap up the question.

There was then a discussion towards the end that had to deal with measuring actual engine conditions in an engine and making that data available for wide use. This was seen as a lacking thing that would help drive transition research.

Okiishi: Thank you Chris. You have made a useful summary of a lot of diverse comments that were hard to reach as consensus on. Anyone from the group wish to add a comment or two?

Hodson: I have a brief comment. Your last statement about "something needs to be measured". The same statement was made at the end of Minnowbrook II, and I suspect Minnowbrook I. Nothing is happening. What is going to make it happen this time?

Murawski: I don't have two million dollars.

Okiishi: What you say is true. There is going to need to be some activity following this meeting. Or it will be just buried in the end. Or it will come to the same conclusion as last time.

Gostelow: What happened to the compressor guys, did they just go to sleep?  
External influences: - birds, hailstones, dust, volcanic ash - more important things - inlet distortion most important.

Okiishi: Paul, we just didn't get that far.

Anon.: Getting back to Howard's comment. If you really want this to happen you need to have more than just a long laundry list. You need to prioritise the list. What exactly do you need measured, and in what priority, and what's the payoff? That's how you start developing advocacy to do it. I'm afraid that if what comes out of here is a general statement, like "we need better measurements of that whole turbine operating environment" it's a motherhood statement that doesn't help. But if you can put together the right motivation, and the priorities in which you want them, I think you can start picking off bits and pieces.

Okiishi: I think it's a point well taken and I think some of the engine companies have already asked those questions and they've got the shortened lists and are going after what they need but this is highly proprietary. So the trick is how do you get this from smaller engine companies and companies that don't have the workforce to pursue these things. And that would be a very tricky thing to do. How do you ask them and how do you get things done?

Narasimha: I think Howard is completely right. This is something we have discussed at the previous two meetings. I actually have read our account of the previous two meetings. What I found was that for Pratt and Whitney, Om Sharma offered a rig that he has for making measurements of the disturbance environment; provided there were people who would work on it he was willing to loan his equipment at no cost. Provided there was money to support the students who would carry out that work. I hope we can make that happen.

Ashpis: We want results from a real engine, not a rig. The turbulence environment may be significantly different.

Narasimha: I don't know exactly what he was offering. I thought it was some schedules in a turbine. Not a real turbine - I don't know how realistic it was.

Anon.: What realistic turbine do you have at Glenn Research Centre?

Ashpis: Following the Minnowbrook II recommendation I looked at what can be done in-house at Glenn. We have at Glenn several combustor facilities and we could measure at the exit of various combustors. However, the real constraint is lack of proper high temperature instrumentation, high frequency response instrumentation that can give us velocities, scales and spectra. We also have a warm turbine rig equipped with can combustors where the temperature is lower, but still beyond instrumentation capabilities. There was an attempt several years ago to measure turbulence in that rig with a hot-wire, but results were inconclusive. Development of special purpose instrumentation is the real challenge; the turbulence measurements will easily follow. Glenn is now funding a project lead by Oldfield at Oxford. The idea is to circumvent the temperature constraint by quickly passing a probe through the hot gas and collecting the data at high speed. This project is in progress, and some experiments were recently completed at a Glenn in a cold freestream turbulence research facility. Another probe to consider is the infinite-tube pressure probe that was originally invented at NASA and developed further at UTRC. This probe was described by Om at the last Minnowbrook. It can measure high frequency pressure fluctuations, but there are still many practical problems with that probe that are being worked on at UTRC. And it is still limited to pressure fluctuations while velocities are of most interest.

As to tests in real engines, I have tried hard to promote the project at NASA and at a couple of joint planning meetings with Wright Lab. I quoted the recommendation made by the international forum of Minnowbrook II. Unfortunately nobody thought it is of high priority. One obstacle is that NASA responds to needs of industry, and industry doesn't put this project on their high priority list. The current fiscal situation at NASA makes it impractical to fund a two million dollar project, particularly if the strongest expression of interest from industry and other government labs is lacking. So it is not that there has not been any effort in this area. But we need to be realistic about what can be done.

Hourmouziadis: There are always two ways of looking at such problems. There are ways of trying to get everything in the best way, in the way that we want to have it. Like getting the disturbances at the exit of a nozzle guide vane, with all turbulence parameters, spectral content and everything. But the other way is trying to do the best with what is available or even measurable in such a situation. The second way is the only way that has been used up until now. Progress was based on what could be done. Why don't we try to do that?

Hodson: For example, do you need to do the full hot turbine to begin with?

Hourmouziadis: Right. We start with a rig. Rear stages have got all the disturbances of the front stage in them.

Okiishi: I think that's partly what you were alluding to, right Tom? You'd got to the designer ask, so that it needs someone to ask that.

Beutner: Part of that is putting a cost to it. It is not just the importance. The key link is addressing high temperature instrumentation, we'll get there slowly. If the cold rig gives you enough of the answer to make a significant advancement and it is cheap, that's where you start.

Gostelow: Compressors are basically cold rigs.

Ashpis: Besides the question if the turbulence environment in rigs represents the turbulence in a real engine, there is a question if cold facilities could be adequate. There is a paper, by Oldfield if I correctly recall, that concludes that turbulence characteristics like scales are unaffected by the temperature, which may enable tests in a cold facility, but this conclusion has been questioned and it is not clear if it is generally correct. Therefore it is not yet clear if information from cold rigs is applicable to hot flows. There are many experiments where the turbulence environment characteristics are not being documented properly. Often it is given only in one point, there are insufficient surveys, and the spectrum is not measured. That is where we have to start, to thoroughly measure the environment in experiments. In many historical experiments this has not been done. It is well known in the history of wind tunnel experiments that a misguided the concept of Unit Reynolds Number was developed, and the reason was the tunnel disturbance environment was ignored.

Anon.: One trend that may not be obvious. It wasn't to me until fairly recently, while working with Pratt and Whitney, is that probably the least sensitive part of the engine, where most of the work is being done now, is not the main gas path, it is all the secondary flow passages. Attachment, separation, transition when it is rotating is very complex and significantly more challenging than the main gas path to predict these things. If you think the main gas path looks scary you should look at the secondary flow passages.

Okiishi: Quite an art - that's a good comment. I think we need to pay attention to what you have just said, it is significant.

Clark: We need to shift funding money to secondary flow passages.

Narasimha: We have discussed these issues several times. Maybe for once we should start at the other end of the problem. What is the data that we would know how to use if we got it? For example in the list that was made the number of parameters was just enormous. Such a large number of parameters you really need to know to characterise the environment. I am quite sure that that large number is correct. But suppose all that information were there. What would we do with it? I think maybe we should start asking that question. What is the information that we are actually in a position to use? In the old days we just thought that free stream turbulence intensity was enough, maybe people would say length scale, now they would say spectrum. But if you are going to see how many chunks of carbon there are, what you are going to do with the hot streaks. What are we going to do with that information?

Okiishi: O.K. Fair comment. One more question? We've been at this for over an hour. It is probably time to declare a minor victory and go and do something else.

Povinelli: By the time we meet again for Minnowbrook Bill Reynolds' twenty million dollar program is going to have solved all these problems.

Durbin: Bill Reynolds' will never solve them, you tell him.

Povinelli: Isn't that what the DoE program was for?

Okiishi: We should all sign up at Stanford? Is that the idea? O.K. well, I think this has been an energetic discussion and that we have accomplished what we set out to do with the working groups.

## WORKSHOP SUMMARY SESSION TRANSCRIPT

**Roddam Narasimha**

Jawaharalal Nehru Centre for Advanced Scientific Research  
Bangalore, India

**Gostelow:** After the first two Minnowbrooks we were very fortunate to have Roddam Narasimha to sum up the meeting and I think we would probably all agree that he gave us some focus, some targets, some objectives, some challenges at those two meetings. I think that has been an important part of the process in keeping things moving and so we had no hesitation whatsoever in inviting Roddam to do the same thing again. He had hesitation in accepting that invitation; he thought he was becoming over-exposed to the media here. I can understand his concerns and his modesty but we assured him we very much wanted him to do the same thing again. So without saying any more I'll say "Roddam, over to you, we look forward to your summing-up".

**Narasimha:** Well, thank you very much for asking me again. As you said I was beginning to wonder whether I should do the same thing again or not. But on the other hand I found that it is useful to myself to sit back and see what actually happened at this meeting and how it compares with what we had said in earlier meetings in the series. I think it would be fair to say that at this meeting I have had less time to collect my thoughts than at the previous meetings. We have not had sufficient time to discuss every issue that came up. So you may find that my summary is a little biased. Maybe there are things that I have forgotten. But I hope that if I write something up I could make a slightly more complete account. So at the present stage this is a personal reaction to what you have heard in the last two or three days. I see that somebody has already done part of my job on the board - is that you, Paul [Gostelow]?

**Gostelow:** Greg Heitland - from industry!

**Narasimha:** Very good - I think that will complement very nicely what I might say here.

So let's start with the topic of turbulent **spots** - which has always been a concern at these meetings, and very rightly I think. Let me begin with a historical note. The spot that appeared in Emmons' first paper on the subject was a sort of kidney-shaped blob; the shape of what we now call the Emmons spot is actually the result of the work of Schubauer and Klebanoff, who made all these nice measurements in a boundary layer in a big tunnel - one of the first quiet tunnels in the world. Now the thing about the Schubauer-Klebanoff spot -and I want to keep coming to this question again and again - is that the associated experiments were made at relatively high Reynolds numbers: we must remember that external aerodynamicists are preoccupied with high Reynolds numbers. No tunnel Reynolds number is high enough for them: I'm sure Jeff [Crouch]

would agree. You get data at wind tunnel Reynolds numbers but that is not flight. Internal aerodynamicists on the other hand do not have this preoccupation about high Reynolds numbers. They are working at low and rather awkward Reynolds numbers, so the fact that they do not always find the Schubauer-Klebanoff spot is not really, from one point of view, such a big surprise. Now during this meeting various questions have been asked, sometimes in the working groups and sometimes in this hall; and some have been radical; e.g. "Do spots occur naturally at all?" Well, I think the answer to that is "Yes", although it was not so categorically given at the time it was asked. In conversations with Greg Walker we recalled what Knapp and others observed with smoke flow pictures taken in a little tunnel. It showed spots similar to the ones we now associate with Emmons and Schubauer. I think that in Terry Jones' data there are also spots that look very similar to the Schubauer-Klebanoff type. I'm sure that in that long smoke tunnel that Mac Head had in Cambridge there were also spots. However it is clear that spots can come in different shapes and sizes, especially when they are not fully developed, which as I said is a pre-occupation of external aerodynamicists. *Sub-critical Emmons spots* (as we may call them) do occur, and can behave in unusual ways, and I think we have had evidence of that in this meeting. If your Reynolds numbers are around the stability limit the spot can either be damped or amplified and this can make for funny shapes.

Now I want to make a brief aside here, and use my privilege as the man who is doing the summing up, by showing you some results on boundary layer stability characteristics that not everybody here may be familiar with. Now it is well known that the laminar boundary layer on a flat plate is unstable, and the stability loop was calculated long ago by Tollmein and by many other people later on. But the non-parallel theories that have been developed in the last fifteen years or so tell us that there is no such thing as a unique stability loop. The stability loop varies with height in the boundary layer because it is non-parallel; or rather you don't have a *loop* – you have a *stability surface*. What is the shape of that surface? Now I hadn't seen a picture of that surface so I have one here for you (Fig. 2). You can think of this red area here as the normal stability loop that you see. The coordinate into the paper is the distance normal to the surface. So the red is near the surface, the blue is somewhere in-between and the green is near the edge. You can see that the stability surface has a very funny shape. You have valleys and ridges here and a near discontinuity here. So it is possible that the disturbance will amplify at some heights in the boundary layer and damp out at others. In the middle is a slice of that stability surface which is crazy; here is what it looks like (Fig. 3). This slice is located roughly where you saw the blue in the previous slide. You can see that it has funny kinks and folds and so on. I show all this only to highlight the fact that disturbances in the boundary layer will not just amplify all across the boundary layer at some specific station: they will amplify at some heights and damp at others till the Reynolds numbers get sufficiently high. So it should not be a surprise that there can be sub-critical spots which are strange in some ways.

Furthermore, we can have distorted spots, we can have sleeves, and spots may be expected to do crazy things in 3-D flows. They can be "blobs" as Paul Gostelow calls them. And the propagation parameters can vary significantly.

Now in Minnowbrook I there was a lot of talk about spot-hunting. Terry Jones and Howard Hodson announced a hunt, but nothing else was said at the last meeting about it so I thought the project had been abandoned. I am very happy to see I was wrong; from the pictures that Terry Jones produced it is nice to see that some of the things we discussed years ago are now actually beginning to happen. So I would like to congratulate the hunters for what they are bringing in, in particular the first measurements of the number of spots per meter per second. It is also nice to see that the measurements are in the right ballpark, so the scaling arguments we have been using without the benefit of direct measurements can't be too bad.

Hodson talked about moving breakdown zones or lines and Frank Smith had very suggestive results from his simple 'half-minute' calculations of inviscid theory. I think it is very important to look at such theories. I was taken by the way that the spots broke up and the way that they showed sudden changes in an adverse pressure gradient. It is quite possible that these are related to the observations that we make in experiments on spots, and to the *sub-transitions* I talked about.

Now **By-Pass Transition**. This is one of the things we have discussed at this meeting. This was always in the background in the previous two meetings as well. And in fact once again I was very happy listening to what was said about the subject at this meeting because a lot of it could be traced to the earlier meetings: I recall the many arguments we had earlier (against the prevailing view), asking why T-S mechanisms must automatically be assumed *not* to operate at high free stream turbulence levels. Jim Kendall was here at Minnowbrook I, with some very interesting results, and so was Morkovin. And we had talked about the role that might be played by T-S mechanisms, operating as transfer functions, filters etc. on a noisy forcing. I think Walker's results at this meeting have shown that there is actually a great deal to all those ideas we discussed. And so I would say that Tollmein has in fact been hiding in the high free stream turbulence level transition that we commonly encounter in turbomachines. There was a lot of discussion about whether we should continue to use the word by-pass, or whether its definition should be changed from the ones currently in use, based exclusively on the values of turbulence intensity. Greg Walker reported on that last night on behalf of his working group. I believe it might still be very convenient to reserve the word 'by-pass' for some mechanism that is non-linear almost from the very beginning, so to speak. For example the disturbances may be so large that the mean flow is affected. In such cases the route followed would be obviously not canonical, and there maybe more significant dynamical changes than in those situations where the high free stream turbulence acts only as a mask.

All of that leads us back to stability, and it is interesting that stability ideas still play such a strong role in terms of giving us insights. We talked about pressure gradients – I'll come back to sub-transitions later. We talked about sub- or super-critical spots. Theophilis' work on global instabilities, the 3D flows that Crouch talked about, Smith's work on spots: all of these show that, unlikely as it may sound, linear stability theory is still teaching us a lot of things. I think that this is fortunate from one point of view, and is actually something that should be pursued a great deal more.

**Direct Numerical Simulation (DNS).** We talked a little bit about DNS at the first meeting, and then at the last meeting we said, "the time has come to undertake a major project on Direct Numerical Simulation". At this meeting, on Monday, there was much scepticism about what DNS could do, and even the suggestion that maybe we shouldn't bother about it. I'm glad that that discussion was undermined completely by the presentation made by Paul Durbin; and even by the great insights obtained from linear DNS work of the kind that Johnson and Theofilis described. I feel that this meeting has already demonstrated that insights from DNS are going to be valuable. For example we had very interesting results presented for a control volume, and I don't think that all the measurements and calculations that have been made earlier had given us that kind of insight. We can argue about what is actually happening there, that is not my point; but DNS has certainly put new thoughts in our minds.

What is the purpose of computing? There was one view here, circulating in this meeting, that it is basically providing reliable numbers. But I remember that many of us who grew up in the early days of computing used to read a pioneering book by Paul Hamming that carried an inscription on the first page saying "The purpose of computing is insight, not numbers". That, of course, people would not agree with now; I would say that we should modify it to say "The purpose of computing is both insight and numbers". Numbers for design from DNS may not happen right now, it may never happen. There is too much numerical information in DNS. But certainly in terms of providing insight I think that DNS is going to be exceptional; we have seen the first evidence of that at this meeting. And in any case it is going to happen, I believe, whether funding agencies support it generously or not. So what we should do, in my view, is not to debate whether DNS should be done or not; the question rather is what are the most interesting things to do.

**Separation bubbles.** Here once again, going over the earlier Minnowbrooks, I think over the last seven years quite a lot has happened. I remember that when I came for the first meeting separation bubbles hadn't been studied for decades after the early work done on wings: we were all talking about what had been done in the 1960s! But now I see that the situation is changing. At the last meeting we had some discussion of the different types of bubbles, when they occur, and so on. At this meeting we had several contributions to understanding the temporal/spatial structure of different types of bubbles; for example interesting data from laser thermal tufts was presented on reattachment. However the thought was going round in my mind about why people were

not discussing the *probabilities* of reverse or forward flow in separating and reattaching flows: we know that separation is intermittent, and we need a separation intermittency distribution. In other separated flows both Roger Simpson and Kida in Japan have made detailed maps of probability distributions, for example in flow past backward-facing steps. We know how these probabilities vary as you go downstream. It is not as if there is a unique reattachment point - there isn't one, and the results that were shown by Theophilis are an indication of what actually happens. On global instabilities I must recall what appears in the lovely pictures in the book by Prandtl and Tietjens - there are all these lumps, and it might be that these lumps we have seen and known about for such a long time might indeed be global instability: this is an interesting thought to pursue.

**Sub-transitions.** There was a lot of discussion here on sub-transitions, including whether that is the right word to use or not and about what is going on. But, as the culprit responsible for introducing this word, I should say that what I have had in mind was that it was something which happened relatively rapidly within the transition zone, making it appear anomalous in some way compared to the canonical high Re transition zone on a flat plate. For example a sub-transition could result from something which happens to the spot after it has been created, because of pressure gradient, Reynolds number, surface geometry, etc. So it is like a sub-plot in this drama of the transition from laminar to turbulent flow. What is happening can be either geometric or dynamic; and spot propagation parameters can change a great deal. They are functions of Reynolds number and of the age of the spot. Once again there is evidence for this in earlier work. Here are some measurements that were made in Bangalore by Rao, nearly 35 years ago. This is the speed of propagation of the spot plotted versus Reynolds number (Fig. 4). What you see here is the spot propagation velocity at the front and the rear of the spot. Values are like 0.85 to 0.9 and 0.5 as the Reynolds number increases, but as the Reynolds number decreases the differences are much smaller, that is to say the growth rates are much smaller. That was actually for a sleeve on an axisymmetric body. We should have curves like that for different kinds of spot. So I think that that can be very important for turbomachinery flows because they are often not fully developed. If subtransition occurs early in the zone fresh breakdowns may occur, and workers from Pratt and Whitney have been arguing that if there are shocks in the flow they may trigger fresh breakdowns. I think that is a possibility to be kept in mind, although if sub-transition occurs later in the transition zone I have difficulty in imagining that further breakdowns can occur in a nearly turbulent boundary layer. One of the things it would be interesting to do, now that these **spot hunting** techniques are beginning to be under control, is to see what happens in sub-transitional flows and also what happens in highly three-dimensional flows.

**Engine Disturbance Environment.** This is also an issue which has been discussed several times here but it seems to me that this is one area in which there has been virtually no progress. If I'm wrong I would like to be corrected by somebody here. But we've discussed this subject again and again and I doubt whether we know any more about it than we did seven years ago. Every time we keep making recommendations that this

should happen, but it doesn't happen. So I come to the conclusion that most people wish that someone else would do it. Now it is going to be a major project and may cost millions of dollars; where are the money and the men to do it? As I mentioned yesterday evening, Om Sharma made an offer last time but as far as I can see it has not been taken up. Much more thinking on the subject is needed. Maybe we need money from both NASA and AFOSR within a business format. I think we need to define more precisely what our priorities should be. In particular we have to decide what we will *do* with the data. Suppose that by some magic some angel came along and gave us all the funding and the people, and that we eventually get loads of data. What difference would that make? I'm not quite sure that we know exactly what to do with that data. So perhaps we should spend a little more effort trying to find out what it is in the disturbance environment that we need to know. Some hard-headed thinking is required here, and some new strategy. I don't know whether the organisers would like to keep that issue open. We can do that but my fear is that next time around, unless some change in thinking takes place, we will still be asking how come we don't know anything more on the subject than we did ten years ago.

Well. There have been a lot of other interesting developments here: e.g. Klebanoff modes, with various numbers now on those modes from Tom Corke, regarding whether they grow in  $x$  and whether the magnitudes change. There has been a lot of work on unsteady transitions and wake passing: Hodson, Durbin, Simon have presented new results. Paul Gostelow had some. John had weighted Strouhal numbers to describe what goes on in such flows. Some work on control of transition was reported by Seifert. Work on models was reported by Dorney, Steelant, Dick, George Huang and others. So there has been a fair amount of that kind of work as well.

Let me just make this final **summary** of what has happened in this meeting so that we can see where we are.

I see that spots continue to occupy our attention. During this meeting and the last one, we are beginning to paint a good portrait of the calmed region. But attention at this meeting has been shifting to young, sub-critical spots and the numbers on spot formation rates that experiments are now beginning to give us. Modelling is still getting attention; last time we discussed early work on unsteady modelling, wake passing transition etc. On Klebanoff modes there was some discussion at the first meeting; there was not as much last time but perhaps now we can quote some numbers. I think on by-pass the scenery is changing, as far as I am concerned in the right direction, so I expect there will be some more insight when we meet next time. Stability continues to be giving us new insights still. On DNS, I personally think the goals that we began setting last time are now on the way to being achieved or even surpassed, although I expect that there will be some differences of view here, and maybe there will be some comments during the discussion. On separation bubbles it seems to me that we have made considerable progress since Minnowbrook II, but on the disturbance environment we have done little.

That would be my summary, a very personal one I'm afraid.

Where do we go from here? What next?

I expect to see more results in coming years on spot identification and spot-hunting, especially in sub-transitional or otherwise anomalous flows, and 3D flows. The time has now come to shift attention to more strongly 3D flows. It is not that everything about 2D flows is understood, but that the big picture is settling down as far as 2D flows are concerned. But 3D flows can give us many surprises so that is one of the things we should spend more time on. I have already said a great deal about DNS, I believe that it is going to happen. I hope that people like Thorwald Herbert will find the patrons they are looking for. Sub-critical spots, blobs, in 3D flows maybe: I think we can expect more of that. We should understand high free-stream turbulence *non-bypass* routes. Perhaps, with the altered perspective on what by-pass may be, we will have a different kind of picture of high disturbance transition routes. I think that we will continue to get insights from stability theory; I will not be surprised if we discover that, just as Mr Tollmein has been hiding on the suction surface of a turbine blade, Mr Goertler will be hiding on the pressure surface: surely we should actually look for those waves. If they are there in turbulent flows I don't see why they are not there in transitional flows, being hidden because of the high free stream turbulence.

I hope that at the next meeting we shall look at these problems, transition in high pressure turbines, on short stubby blades, in 3D flows and so on. These are messier flows, than the nearly 2D flows that low-pressure turbines experience, but I do think there might be many fascinating things may happen there!

So the number one area that I think we should emphasise may be 3D flows, perhaps with DNS. That's a very personal view, and I thank you for asking me to share them with you.

**Gostelow:** We now have a few minutes for discussion and any questions. For anyone to attack Roddam or describe any ideas you might have. We'll cut it off pretty quickly but if you have questions feel free to go ahead and ask them

**Hourmouziadis:** It is not a question. I was wondering if we should not use DNS as a simple numerical experimental tool. For example we should pick out very simple flows, like flat plate with pressure rises, and have a look at the spots and calming zones and try to understand how this materialises. At present we still have the most detailed results from Paul's experimental work. I think we should put that together to understand how this thing works.

**Durbin:** I have work in that area that has been funded; as soon as I find a student I'll be working on that and I think you are absolutely right. It is an experimental tool and can generate data just like a laboratory experiment. It is a mistake to think of it as a design tool but it is correct to think of it as an experimental tool.

**Narasimha:** I just want to go back to a suggestion that was made last time, that we should in fact pick certain well-defined situations, do a DNS, dump the data that comes out so that it is available for everybody to analyse. So if somebody has taken the trouble to make a solution for situations that a group can identify, and the data is openly available, then I think a lot of analysis could be done which may be very useful. I think we were generally agreed on that last time but on Monday it seemed that people were not intending to proceed along those lines. I believe that would be a mistake.

**McEligot:** Last time you were suggesting that we take a particular airfoil shape and do DNS calculations at a Reynolds number of, say, 50,000 based on chord. Paul essentially has done that except I get the impression that he has confused it by putting wakes in front.

**Durbin:** I've done it both with and without the wakes but it is a lot more interesting with the wakes.

**Narasimha:** Paul has done more than we set out to do! That's wonderful.

**Simon:** Can we use Mann Rai's calculation that has already been done? That is a simulation of the Sohn & Reshotko flat-plate experiment. And just go back and do some data mining that we haven't done yet.

**Durbin:** We've done that T3A case that I didn't show. I don't think Mann Rai had enough resolution as he indicated in his paper: he mentioned that at Minnowbrook II.

**Theophilis:** Whether it is stability analysis or DNS we should pay more attention to proving ourselves useful to these people, although it is very nice to go all the way with analysis and for me personally it has been very enriching.

**Okiishi:** I think that for the future I would personally like to see more questions asked about the role of the kinds of instabilities that we talked about at this meeting. What I would call turbomachine instabilities. Stall, surge and these kinds of phenomena. I don't know the answers but I have a feeling that some of the knowledge that we saw displayed here would be useful in helping product designers to avoid those surprises that detract from reliability because you don't expect them and then they happen. Then we have a whole re-engineering program. The other thing I would point out would be what Thorsten brought out which is the aeroelasticity drivers. On the one hand we have the response people who are looking at the blades and what they are doing, but I think there

are drivers that may have fundamentally some relationship with knowledge about transition. This is not a criticism but an addition to your list. These are some unknowns in product design that people who've thought about it know more about and can get a handle on.

**Gostelow:** Can I support what Ted has said and say that I would like to have seen compressor and fan problems added to that list as well as the HP turbine because I think there is possibly more scope there, especially with regard to stability. Greg, tell us about your wall chart.

**Heitland:** This is our current design cycle in turbine aero. You would find a very similar process in compressor aero design. The engine cycle in the middle is what drives the whole process. The first to feed into that is the 1D code. This is a highly calibrated empirical tool, plus this magical technology adder, which management sees as our CFD tools. Every year for every new design that adder gets bigger and bigger. We go through a fairly standard process of a 2D code which feeds into an airfoil geometry code to design on streamlines. Then we come to do a quasi-3D code for quick iterations on designing the airfoil shape; we iterate back and forth to get airfoil geometry in quasi 3D then we go to our 3D steady viscous code, using the  $k-\epsilon$  models, but probably the most popular in our area is Baldwin-Lomax. Then finally as a last check we'll kick out to the multi blade row 3D steady code. But the trick is we don't know what our turbulence intensity is. We don't know what to put into that value. We could maybe guess. Nor the length scale. These determine whether the airfoil separates or not. We can get it to separate depending on the turbulence intensity level we put in. This is a big problem.

**Gostelow:** Do you want to match Om Sharma's offer last time and provide an engine fully instrumented and bring the results along to Minnowbrook IV? Can we tempt you to that?

**Heitland:** I don't carry the clout that Om Sharma carries in our company.

**Hourmouziadis:** The 2D design they are using in the quasi 3D system. That's a Navier-Stokes code?

**Heitland:** It's the MISES code.

**Hourmouziadis:** Do they have any laminar flows there? Will it predict transition?

**Heitland:** It's somewhere in between.

**Hourmouziadis:** I didn't think there was anything in between.

**Heitland:** You'd be surprised.

**Durbin:** If you go to any engine company you'll see exactly the same thing. Exactly the same machinery, exactly the same use of codes, and they are increasingly wanting to rely on CFD and they are increasingly needing models. When they talk about length scale what they actually mean is  $\epsilon$ , not correlation length scale, and I think there is an extent to which Roddam maybe actually underplayed the modeling. That was one line "modeling" then go on. But that's really where they need the help. When they support experiments they say "do the experiment that we need to go into the modeling". Maybe there should be a shift to recognising that the product, from the academic level, is at least the basic models and then they tally them to their needs. I think there should be more of that focus. It's like a question you asked "If you had the data what would you do with it?" Or to rephrase that "What data do you need to go into these models?" But the answer is that the question you raised – "If I had the data what would I do with it?" means "How would I put that into a model?"

**Narasimha:** My point was not to say what should not be done but rather to express the feeling that sometimes when people ask for length scales or something it is not absolutely clear to me that that is what is going to provide the answer. And it may well be that some experiment tells us that that is not what we should ask for – perhaps we should ask for something else. And this has happened again and again so we should always keep that in mind as well. For example, what we heard about by-pass is an excellent instance. In an earlier meeting in this same hall we have heard that up to 2% f.s.t. is one regime, 2-4% is another thing, 4-15% is yet another thing and so on. But in the light of work that has been done in between, and in particular Greg Walker's presentation, we now see that that may not be the way to look at it. The people making models have a very hard task on their hands, and there is always the possibility that we are not asking the right questions. In terms of by-pass, if someone comes and says, "You just give me the free stream turbulence and the length scale and I will do everything else", I am not sure that is enough. We just have to keep that in mind, that is all I am saying.

**Gostelow:** May I just say that I think this raises the question of whether we have a Minnowbrook IV, and of what the balance is. I think this has always been a balancing act. We work with our sponsors and with you folks whose support we appreciate. We started out very much with the concept of a balance between the fundamental transition community and the turbomachinery community, who hardly ever got together, and we wanted to get half of each of them in this room and bash their heads together, and it worked. The question is whether that's the way to go, or whether we focus on the engine industry, or what? I don't want you to answer that right now but I do want each of you to think about this and get your views in to John or Terry or myself so that if we do have a Minnowbrook IV, and let us know whether you think that is a good idea or not, then we know how to get it just right so that we are serving your interests, and the interests of the people who are supporting us. So let me raise that as a question.

**Hodson:** Can I pick up on what you have said, and to a certain extent what Paul Durbin has said. I don't think you can actually use the words data and models in the same sentence. Perhaps you didn't mean that, I don't know. But I think it actually hits the nail on the head. What industry wants is, forgive me if I'm putting words in your mouth, quick fast dirty solutions. And that is very different from the sort of stuff we are seeing from the fundamentalists, the true modelers. I think anything else is correlations. We can disguise it and call it what we like but really it is data being used to represent what we think might be happening. And I actually don't see that much convergence. Although Minnowbrook I, II and III have worked in the sense of bringing us together, I don't see much convergence.

**Gostelow:** Would you like to see more convergence?

**Hodson:** I think we have to.

**Okiishi:** Right across the border in Vermont there's a guy who operates a company. Their business is to design turbomachines. The puzzle to me has been the engine companies all have secrets. And they don't want to come to this meeting and reveal what their hands are like, so they are going to be careful by saying what they need in the way of design helps or new models and so forth. If you take a guy like Japikse, who owns Concepts, here he is trying to broaden his expertise as far as what he can do to design turbomachine x, turbomachine y, a wide variety of turbomachines. It would be interesting to bring him to this meeting. Have him maybe keynote it and say "Here is where we are at design-wise, this is what I think we need" and then have him sit here for two or three days and at the end like you, Roddam, say "Now I have some insights, what a gold mine, there is so much knowledge here. I'd like to tap all of you to help me become a more successful designer". He doesn't have secrets in this way, he wants to have that knowledge, and he is not ashamed or afraid to tip his hand a little bit and to say, "We are ignorant here and we don't know how to do this quite." That could be a possible tack to bring this convergence.

**Hodson:** I think you are being too nice. We've got people from industry here, why not ask them now?

**Okiishi:** I know, but everybody from industry has to be a little bit cautious.

**Hodson:** Well they can tell us if they are holding back.

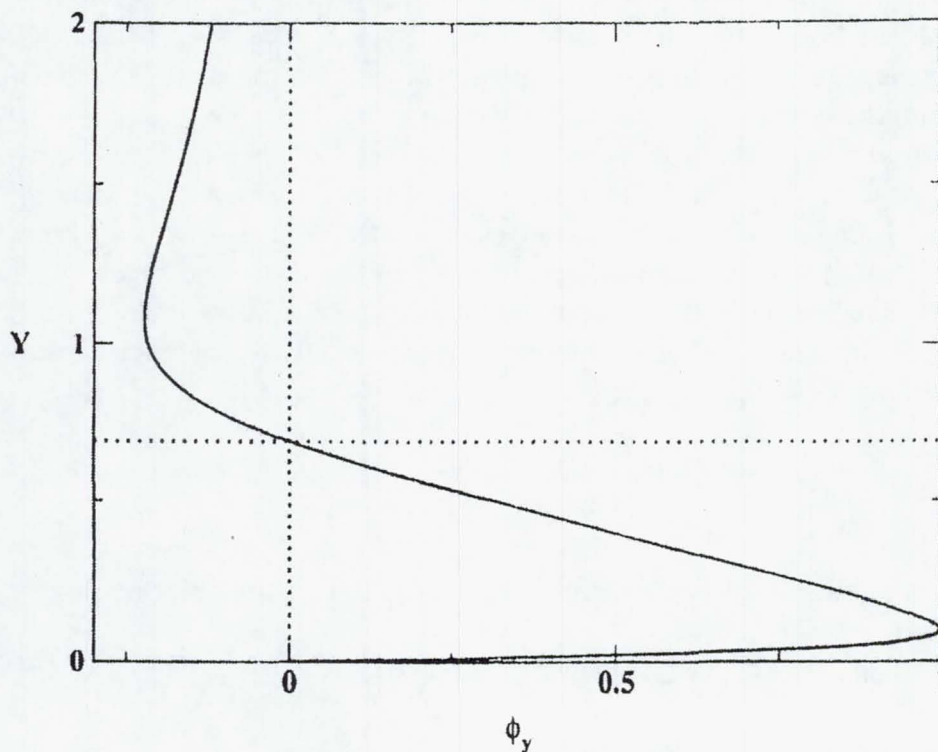

**Gostelow:** Are you holding back?

**Heitland:** I'll spill my guts. (Laughter).

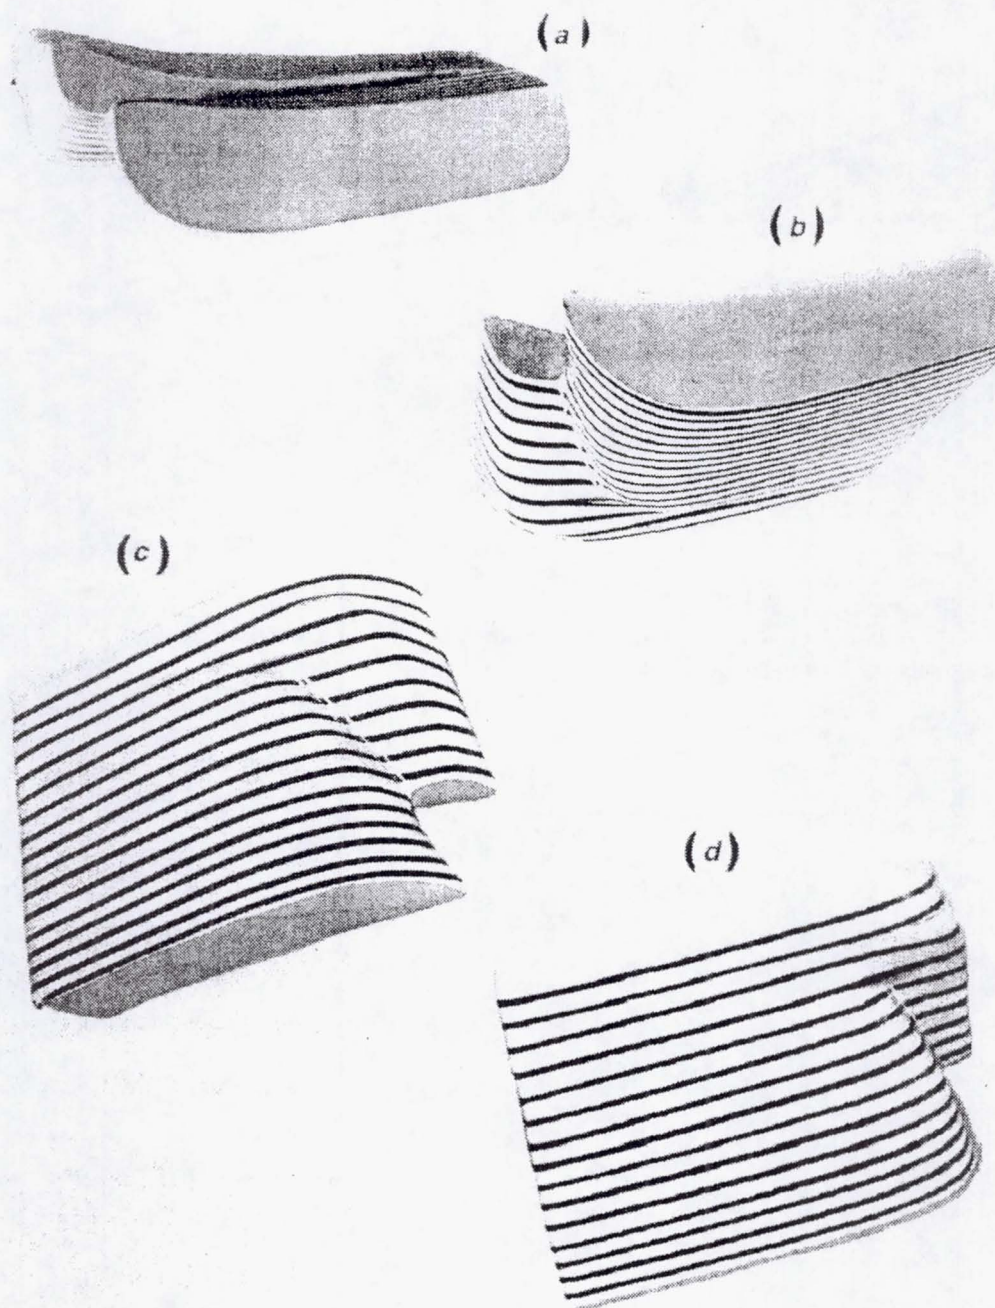

**Okiishi:** We are missing that element - the design chiefs are not here.

**Gostelow:** O.K. Thank you for that. That has been a good discussion. I want to conclude by thanking Roddam. Roddam got us off to a provocative start on his favourite subject of sub-transitions and really got the ball rolling very well. He has wrapped things up very nicely and again I think set you some interesting challenges and asked you some good questions. So I would like you to join me in thanking Roddam. We have to conclude there. Thank you all for coming and I hope you've enjoyed it.

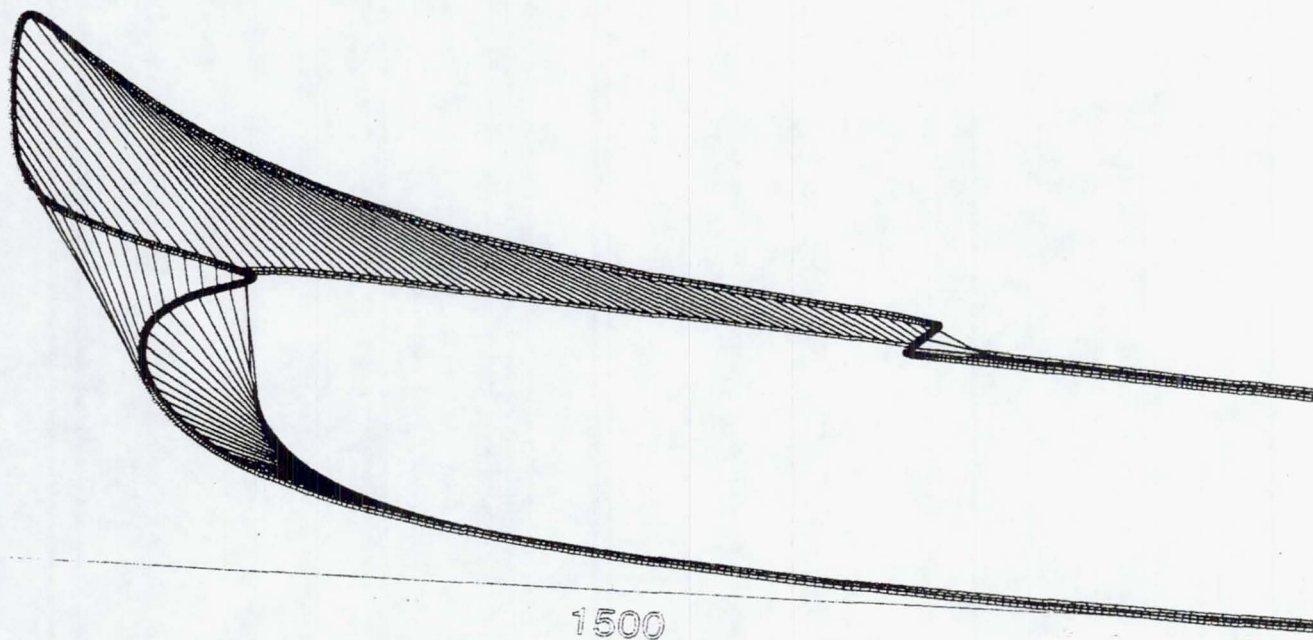

**Narasimha:** Before you go I think we should thank the three organizers, John LaGraff, Paul Gostelow and Terry Jones for organizing another splendid meeting in this series.

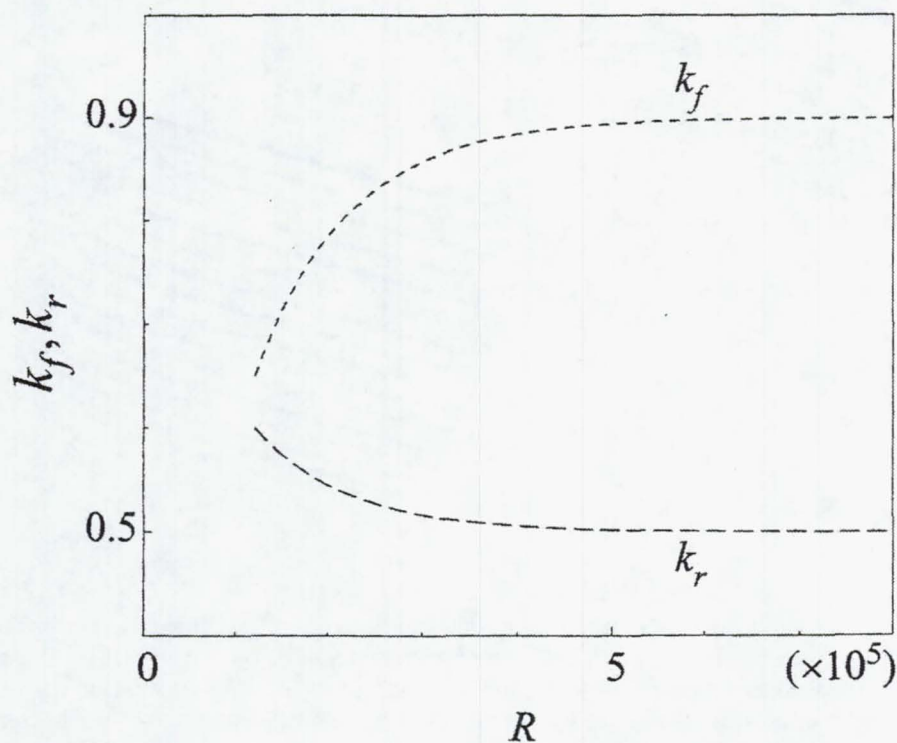

**Figure 1.** Typical eigenfunction for the Blasius boundary layer, showing the three zeroes respectively at the wall, at infinity, and at an intermediate point.

**Figure 2.** Four views of the stability surface for the Blasius boundary layer, in  $(y, \omega, R)$  space. The surface is generated by stacking up, along the  $y$ -axis, stability loops generated at various values of  $y$ . The red surface is close to the wall, the blue surface is near the intermediate zero, and the pink surface is near the top of the eigenfunction shown in Figure 1. (a) View with  $R$  to the right,  $\omega$  towards the top and  $y$  into paper. The red region is close to the unstable regime shown in the classical Orr-Sommerfeld stability loop. Note the barely discernible cut-back near the blue loop (shown in greater detail in Figure 3). (b) View from below, showing the lower branches of the stability loop stacked along  $y$ . (c) and (d) Other views, chiefly of the lower branches, showing the valley and ridge nature of the topography of the stability surface.

**Figure 3.** A slice of the stability surface of Figure 2, taken around the blue loop, bounded by  $y = 0.69, 0.70$ . The axis shown in  $R$ . Note the fold-back on the upper branch.

**Figure 4.** Schematic of variation with Reynolds number of the velocities of the front ( $k_f$ ) and the base ( $k_r$ ) of a turbulent spot.

## LIST OF PARTICIPANTS

Mr. Richard Anthony  
Osney Labs-Oxford University

13. ABSTRACT (Maximum 200 words)  This volume and its accompanying CD-ROM contain materials presented at the Minnowbrook III-2000 Workshop on Boundary Layer Transition and Unsteady Aspects of Turbomachinery Flows held at the Syracuse University Minnowbrook Conference Center, Blue Mountain Lake, New York, August 20-23, 2000. Workshop organizers were John E. LaGraff (Syracuse University), Terry V. Jones (Oxford University), and J. Paul Gostelow (University of Leicester). The workshop followed the theme, venue, and informal format of two earlier workshops: Minnowbrook I (1993) and Minnowbrook II (1997). The workshop was focused on physical understanding the late stage (final breakdown) boundary layer transition, separation, and effects of unsteady wakes with the specific goal of contributing to engineering application of improving design codes for turbomachinery. The workshop participants included academic researchers from the USA and abroad, and representatives from the gas-turbine industry and government laboratories. The physical mechanisms discussed included turbulence disturbance environment in turbomachinery, flow instabilities, bypass and natural transition, turbulent spots and calmed regions, wake interactions with attached and separated boundary layers, turbulence and transition modeling and CFD, and DNS. This volume contains abstracts and copies of the viewgraphs presented, organized according to the workshop sessions. The viewgraphs are included on the CD-ROM only. The workshop summary and the plenary-discussion transcripts clearly highlight the need for continued vigorous research in the technologically important area of transition, separated and unsteady flows in turbomachines.
